Indirect Inference with Endogenously Missing Exogenous Variables *

Saraswata Chaudhuri†, David T. Frazier‡, Eric Renault§

December 30, 2015

Abstract
We consider consistent estimation of parameters in a structural model by Indirect Inference (II) when the exogenous variables can be missing at random (MAR) endogenously. We demonstrate that II procedures which simply discard sample units with missing observations can yield inconsistent estimates of the true structural parameters. By inverse probability weighting (IPW) the “complete case” observations, i.e., sample units with no missing variables for the observed and simulated samples, we propose a new method of II consistently estimates the structural parameters of interest. Asymptotic properties of the new estimator are discussed. An illustration is provided based on a multinomial probit model. A small scale Monte-Carlo study in this model demonstrates the severe bias incurred by existing II estimators, and its subsequent correction by our new II estimator.

Keywords: Indirect Inference; Missing at Random; Inverse Probability Weighting

1 Introduction

Since the seminal work of Smith (1990, 1993), Gourieroux et al. (1993) and Gallant and Tauchen (1996), Indirect Inference (II) has been used for estimation in a variety of structural models where direct computation of likelihood functions is difficult but simulation based on the structural model is relatively straightforward. Altonji et al. (2013) have recently remarked that in some circumstances “accommodating missing data in II is straightforward: after generating a complete set of simulated data, one simply omits observations in the same way they are omitted in the observed data”. Our focus of interest in this paper is precisely a case where this argument is invalid due to the impossibility of simulating data with a mechanism for missing data that properly mimics the actual missing data mechanism in the Data Generating Process (DGP). As stressed by Jiang and Turnbull (2004) (Section 3.4), when data are not “Missing Completely At Random” (MCAR), the key tool of II, namely the bridge relationship (resp. binding function) in Jiang and Turnbull (resp. Gourieroux et al.) terminology, may be impossible to infer from simulations.

Generally speaking, II sets the focus on estimation of structural parameters $\theta \in \Theta \subset \mathbb{R}^d_\theta$ through an intermediate or auxiliary statistic that consistently estimates the true unknown value $\beta^0$ of some auxiliary parameters $\beta \in \mathcal{B} \subset \mathbb{R}^d_\beta$, $d_\beta \geq d_\theta$. For sake of expositional simplicity, we always define the true unknown value $\beta^0$ as the unique solution of some moment conditions

$$E[m(W,X,\beta)] = 0,$$

where $W$ and $X$ are random vectors. The vectorial function $m(.,.,.)$ is known and can be assumed without loss of generality to be of dimension $d_\beta$.

Let $\{W_i, X_i\}_{i=1}^N$ stand for an i.i.d. sample drawn from the distribution of $(W,X)$. The vector $W_i$ (resp. $X_i$) could include components corresponding to different time points for the $i$-th sample unit, and in this sense our setup allows for panel data (large $N$, small $T$). However, for simplicity we will not pursue this aspect further.

We are interested in the case where the statistician does not observe $(W_i, X_i)$ for all $N$ sample units, with the particular structure of the missingness being characterized by observing only a subsequence of the complete sequence $\{X_i\}_{i=1}^N$. Following common practice, it is useful to define a binary random variable $D_i$ with $D_i = 1$ when the vector $X_i$ is observed. In other words, the statistician knows the random subset of indices $i \in \{1, 2, ..., N\}$ for which $X_i$ is missing, which corresponds to the set of indices such that $D_i = 0$.

We maintain throughout the assumption that data are “Missing at Random” (MAR). Following Rubin (1976), data are MAR when “the conditional probability of the observed pattern of missing data, given the missing data and the value of the observed data, is the same for all possible values of the missing data”. With our notations, we enforce this condition by assuming that almost surely

$$\Pr[D = 1|W, X] = \Pr[D = 1|W] > 0.$$

Note that Wooldridge (2007) stresses the relevance of an extension of assumption (2) (see Wooldridge’s Assumption 3.1. (iv) p 1283) to also allow some components of the vector $W_i$ to be unobserved whenever $D_i = 0$. In the context of II, this extension is immaterial as long as the components of $W$ impacted by the missing data mechanism are only endogenous variables.
Generally speaking, if the above missing data mechanism only pertains to endogenous variables then the sanguine statement of Altonji et al. (2013) quoted above regarding the easy treatment of missing data in II is valid.

The focus of interest in this paper is a case where the solution put forward by Altonji et al. (2013) does not work, precisely because the missing data mechanism pertains to exogenous variables that we denote by $X$ and which we are not keen to simulate (see Section two for a more precise discussion). To emphasize our focus on missing exogenous variables, albeit endogenously missing since they are not MCAR, we will dub throughout the maintained assumption (2) the **MAR-X** property.

Under **MAR-X**, the missing data problem is that sample counterparts of the moment conditions (1) can only be deduced from the “observed” or “complete case” units $\{D_i \cdot m(W_i, X_i, \beta)\}_{i=1}^N$; i.e., when $X_i$ is not observed, all we know is that it is unobserved ($D_i = 0$) and we cannot compute $m(W_i, X_i, \beta)$. Then, revisiting the moment conditions (1) as the following “observed” moment conditions

$$E[Dm(W, X, \beta)] = 0$$

would obviously lead to the textbook issue of selection bias. However, the issue with the use of (3) for II differs from the textbook presentation (see, e.g., Little and Rubin, 2002 and Wooldridge, 2005 ) in at least two respects.

First, our focus of interest is not direct estimation of $\beta$ but rather indirect estimation of structural parameters $\theta$ through auxiliary parameters $\beta$. Second, unlike direct inference with missing data, the key necessary condition for validity of II is the ability of the simulated data to mimic the estimates of the auxiliary model obtained from the observed data, irrespective of what this model is. In this respect the important issue for simulation based inference is not the difference between conditions (1) and (3), but to what extent this difference can be accounted for in our simulation-based inference procedure.

While it may be possible to accommodate the consequences due to the differences between (1) and (3), see Section two for specific details, our main goal is to modify the “observed” moment conditions (3) into moment conditions, that are “observed” and conformable to the initial moment conditions in equation (1). To do so, the key idea is to use the maintained **MAR-X** assumption to revisit (3) as (possibly misspecified) conditional moment restrictions given $W$ and to resort to a well chosen instrumental variable $h(W)$, leading to the “observed” moment conditions

$$E[Dh(W)m(W, X, \beta)] = 0. \tag{4}$$

Defining the true unknown propensity score as $p_0(W) = \text{Pr}[D = 1|W]$, equation (4) will be conformable to the initial moment conditions of interest that define $\beta^0$ if, for all $\beta \in B$,

$$E[Dh(W)m(W, X, \beta)] = E[p_0(W)h(W)m(W, X, \beta)] = E[m(W, X, \beta)],$$

where the first equality follows from the Law of Iterated Expectations (LIE) and **MAR-X**. Equivalence between moment conditions (1) and (4) then requires, by the LIE, for all $\beta \in B$,

$$E [{1 - p_0(W)h(W)} E[m(W, X, \beta) | W]] = 0. \tag{5}$$

The identity in (5) encapsulates the two main cases of interest. First, following Wooldridge.
(2007) (see Assumption 4.1 page 1288), one may maintain the assumption of "exogenous selection", meaning that at \( \beta^0 \), the solution to (1), actually satisfies

\[
E[m(W, X, \beta^0) | W] = 0.
\] (6)

Our focus of interest is precisely the case where selection is not exogenous. In addition, it should be noted that this "exogenous selection" assumption amounts to a structural assumption on the auxiliary model used in II, which is somewhat logically inconsistent with the idea of an auxiliary model:¹ When performing II one has in mind indirect estimation of a structural model through a purely instrumental auxiliary model that is not endowed with any kind of structural belief.

Second, if the exogeneity assumption is not maintained, the conditional expectation computed in (6) may be any function of \( W \) since we do not want to maintain any restrictive assumption about the probability distribution of the exogenous variables \( X \). As a result, the only way to get the identity in equation (5) is to choose the "instrument" \( h(W) \) inversely proportional to the propensity score \( p_0(W) := \Pr[D = 1|W] \); that is, to rewrite our auxiliary model in (1) as the moment conditions

\[
E \left[ \frac{D}{p_0(W)} m(W, X, \beta) \right] = 0.
\] (7)

The equivalence between moment conditions (1) and (7) is precisely due to the (assumed) validity of the MAR-X assumption.

While IPW has a long history in statistical inference with missing data, see, e.g., Horvitz and Thompson (1952) and Robins et al. (1994), this paper constitutes, to the best of our knowledge, the first use of IPW within simulation based inference with endogenously missing exogenous variables. While seemingly different from its historical use, the IPW strategy in this research is underpinned by the maintained MAR-X hypothesis that has found recent use in economics and econometrics. See, among others, Hirano et al. (2003), Chen et al. (2005), Chen et al. (2008), Graham et al. (2012) for cases where the missingness pattern is similar to ours, while Cattaneo (2010) and Chaudhuri and Guilkey (2014) consider more involved patterns of missingness. All of the above papers use some form of MAR-X to correct for the selection bias in moment conditions used within estimation, as is done herein.

However, unlike missing data in direct inference, because II can only conditionally simulate data given all exogenous variables, the simulation step of II induces dependence between the simulated endogenous variables and the missingness indicator that is not present in the observed data. As a direct consequence, the standard IPW-based arguments for direct inference outlined above is not valid for the simulated counterpart. However, we detail a novel identification argument (see Section two) that uses IPW, along with the MAR-X assumption and a particular simulation design, to (jointly) identify the auxiliary parameters based on the simulated data. Together, these two IPW-based steps allow us to identify the structural parameters of interest.

The paper is organized as follows. Our preferred II strategy with MAR-X exogenous variables as well as possible alternative strategies are discussed in Section two. Section three details implementation of this new II strategy, states the asymptotic theory of our II estimator and pro-

¹The "exogenous selection" assumption in (6) actually extends Wooldridge’s (2007) definition for M-estimators to the case of general estimating equations, which could correspond to the first order conditions of some M-estimator.
poses an alternative implementation of our approach based on the generalized indirect inference (GII) approach of Keane and Smith (2005). In Section four, we illustrate our new approach in a multinomial probit model similar to Section nine of Gourieroux et al. (1993) and model four of Keane and Smith (2005). However, due to the missing data problem, we carefully revisit identification of the structural parameters. Section four also contains a small scale Monte Carlo experiment illustrating the performance of our approach in a multinomial probit model. Given the non-smoothness of the binding function in the multinomial probit model, we also consider a GII implementation of our approach. The Monte Carlo results provide compelling evidence on the performance of our II strategy and its GII implementation. Section five concludes and proofs of the theoretical results are collected in the appendix.

2 II with MAR Exogenous Variables

We sketch in Section 2.1 the general problem of II in the presence of missing data. The usefulness of the MAR-X assumption for performing II is made explicit in Section 2.2. Since Section 2.1 simply sketches the different possibilities, precise definitions of certain terms are only provided in Section 2.2.

2.1 Indirect Inference with Missing Data

To fix ideas, we focus on the simple structural model

\[ Y = r(Z, X, \varepsilon; \theta), \]  

(8)

where \( r(.) \) is a vector valued function known up to the finite dimensional parameter \( \theta \in \Theta \subset \mathbb{R}^{d_{\theta}} \). \( \varepsilon \) is the unobserved stochastic error whose probability distribution is assumed (without loss of generality) to be known. \( Y \) denotes the endogenous variables while the variables \( X \) and \( Z \) are independent of \( \varepsilon \) and treated as exogenous. We maintain that it is not desirable to assume that the distribution of \( X \) and \( Z \) (conditional or unconditional on \( Y \)) is known. Let \( \theta^0 \in \Theta \) be the true value of \( \theta \) in our population of interest.

Let us first consider simulation of data from the structural model (8) when there is no missingness. Let \( \tilde{\varepsilon} \) be a random variable drawn from the distribution of \( \varepsilon \) and independent of \( W = (Y', Z')' \) and \( X \). For the given \( \theta \in \Theta \), consider the variables \( Y(\theta) \) simulated from equation (8): \( Y(\theta) = r(Z, X, \tilde{\varepsilon}; \theta) \).

For a given value \( \theta \in \Theta \) used to simulate the endogenous variable \( Y(\theta) \), II defines the binding function \( \beta^0(\theta) \) as the solution, in \( \beta \), to the simulated counterpart of moment conditions (1):

\[ E [m(Y(\theta), Z, X, \beta)] = 0. \]  

(9)

If \( \theta \mapsto \beta^0(\theta) \) is injective, \( \theta^0 \) is the unique \( \theta \in \Theta \) satisfying \( \beta^0 = \beta^0(\theta) \). Implementation of II is generally based on the finite sample counterparts of equations (1) and (9) obtained as sample averages of the observed and simulated data.

As mentioned in the introduction, it may sometimes be argued that missing data is immaterial for II, since it is always possible to purposefully omit observations in the simulated sample in
the same way they are missing in the observed data. In other words, selection bias introduced
when using the observed moment conditions

\[ E[Dm(Y, Z, X, \beta)] = 0 \]

may be inconsequential, since after all, if all variables \( Y, Z, X, D \) can be simulated, where, with
an abuse of notation we let \( \theta \) denote all unknown parameters governing the simulation process,
we can define the binding function \( \theta \mapsto \hat{\beta}(\theta) \) as the solution of the simulated counterpart

\[ E[D(\theta) \cdot m(Y(\theta), Z(\theta), X(\theta), \beta)] = 0. \]

However, our focus of interest in this paper renders the above solution infeasible for several
reasons.

First, since we are unwilling to assume a distribution for the exogenous variables \( X, Z \),
obtaining simulated counterparts \( X(\theta), Z(\theta) \) of \( X, Z \) is not feasible. As alluded to above, it
is somewhat logically inconsistent to specify a probability distribution for exogenous variables.
Moreover, as shown by Gourieroux at al. (1993), there is an efficiency gain to use for II a
simulated path in which, along with simulated endogenous variables, we keep exogenous variables
at their observed values in the actual data set. It is precisely this exogeneity property that makes
this practice valid.

Second, when the endogenous variables are missing but the exogenous variables are not
missing, if one fixed the exogenous variables at their observed values, the binding function for II
could be defined as the solution to

\[ E[D(\theta)m(Y(\theta), Z, X, \beta)] = 0, \]

where \( \theta \) again denotes all unknown parameters governing the simulated process. Such a practice
would only be accurate if we were to treat both \( Y \) and \( D \) as endogenous, with \( Y(\theta) \) and \( D(\theta) \) simulated according to an augmented analog of the structural model in (8). However, simulation
of \( Y(\theta) \) and \( D(\theta) \) is not feasible in our context since the missing data mechanism pertains to the
exogenous variables \( X \) and so for observation \( i \) the endogenous \( Y_i(\theta) \) cannot be simulated when
\( D_i = 0 \).

This inability to simulate \( Y(\theta) \) when \( D = 0 \) also ensures that II based on the “observed” or
“complete case” moment conditions

\[ E[Dm(Y, Z, X, \beta)] = 0 \]
\[ E[Dm(Y(\theta), Z, X, \beta)] = 0 \]

will not, in general, identify \( \theta^0 \). Identification would require that the joint distributions of
\( (D, Y, Z, X) \) and \( (D, Y(\theta^0), Z, X) \) be equivalent. However, this cannot be true in general for the
following reason: the simulated error \( \tilde{\epsilon} \) used to generate \( Y(\theta^0) \) is, by construction, independent
of \( D \), whereas the MAR-X assumption does not demand independence between \( \epsilon \) (structural
error in Y-equation) and \( D \), either unconditionally or conditional on \( X \) and \( Z \). Hence, unless \( D \) is independent of \( \epsilon \), which, in turn, rules out endogenous missingness of \( X \), one cannot identify \( \theta^0 \)
following the above approach except by happenstance. To further clarify this idea of identification
failure, we refer the interested reader to Section 4.1 for a toy example that illustrates this failure in a simple probit model.

Interestingly enough, this double hurdle of data missingness may actually suggest to modify the binding function even more by considering the simulated moment conditions:

$$E[D \cdot D(\theta) \cdot m(Y(\theta), Z, X, \beta)] = 0.$$ 

While this complicated simulated missing data mechanism may actually provide a feasible solution (see Chaudhuri et al. (2015)), our focus of interest in this paper is rather to remain true to the initial auxiliary model and moment condition in (1) by considering its “observed” counterpart

$$E \left[ \frac{D}{p_0(W)} m(W, X, \beta) \right] = 0.$$ 

While we have stressed in the introduction that it is the MAR-X assumption that makes this IPW auxiliary model equivalent to the initial one, more importantly the MAR-X assumption allows us to define a conformable binding function II without resorting to simulation of the missingness indicator D.

### 2.2 II Based on IPW Under MAR-X

The use of the MAR-X assumption made in the introduction, albeit non-standard because of its use in the auxiliary model, corrects for the effect of selection bias in the identification of the auxiliary parameters $\beta$; that is, for all $\beta \in \mathcal{B}$, we have, by the MAR-X assumption

$$E \left[ \frac{D}{p_0(W)} m(Y, Z, X, \beta) \right] = E \left[ E \left[ \frac{D}{p_0(W)} W, X \right] E \left[ m(Y, Z, X, \beta) \left| W, X \right. \right] \right] = E \left[ m(Y, Z, X, \beta) \right]. (10)$$

The key property for performing II using the auxiliary model based on moment conditions (10) is to ensure the resulting binding function will properly match. This matching will require that, for all $\beta \in \mathcal{B}$ and for all $\theta \in \Theta$,

$$E \left[ \frac{D}{p_0(W)} m(Y(\theta), Z, X, \beta) \right] = E \left[ m(Y(\theta), Z, X, \beta) \right]. (11)$$

Demonstrating satisfaction of (11) requires a more precise study of the expectations used above. In equation (10) the notations are straightforward: expectations are computed with respect to the joint distribution of $(D, Y, Z, X)$ given by the data generating process (DGP). In (11) the expectation operator is more complicated since it involves jointly the DGP for the observed and simulated data. To highlight this difference, we analyze each case in turn, starting with the observed data.

The observed data $\{D_i, Y_i, Z_i, D_iX_i\}_{i=1}^N$, where $D_iX_i = 0$ if $D_i = 0$ and $X_i$ else, can be seen as the output of the following mechanism:

(O1) A sample of exogenous variables $\{Z_i, X_i\}_{i=1}^N$, possibly partially latent, is generated by a completely unknown DGP.
(O2) A sample of i.i.d. stochastic errors \( \{\varepsilon_i\}_{i=1}^N \) are drawn from the known probability distribution of \( \varepsilon \), with all draws independent of \( \{Z_i, X_i\}_{i=1}^N \).

(O3) Endogenous variables \( \{Y_i\}_{i=1}^N \) are observed as a result of the DGP: \( Y_i = r(Z_i, X_i, \varepsilon_i; \theta^0) \), with \( \theta^0 \) the true unknown value of the structural parameters.

(O4) A vector \( \{D_i\}_{i=1}^N \) is drawn in the product of conditional distributions of \( D_i \) given \( \{Y_i, Z_i\}_{i=1}^N \). Moreover, these conditional distributions, for \( i = 1, ..., N \), are assumed (by MAR-X) not to depend on \( X_i \) when conditioned on \( W_i \).

For the simulated data, a similar procedure is implicitly considered when simulating the endogenous variable. However, unlike step (O2) above, for some integer \( S \geq 1 \) we draw \( S \) independent simulated samples of i.i.d. errors \( \{\tilde{\varepsilon}_{is}\}_{s=1}^S \) from the known probability distribution of \( \varepsilon \) with \( \{\tilde{\varepsilon}_{is}\}_{i=1}^N \) independent of \( \{\varepsilon_i, Z_i, X_i, D_i\}_{i=1}^N \) by construction. Given, \( \{\tilde{\varepsilon}_{is}\}_{i=1}^N \), and in accordance with (O3) above, we define, for all \( \theta \in \Theta \): \( Y_{is}(\theta) = r(Z_i, X_i, \tilde{\varepsilon}_{is}; \theta) \). The simulation step produces a sequence \( \{Z_i, D_i, X_i, \varepsilon_i, D_i, \tilde{\varepsilon}_{is}\}_{i=1}^N, s = 1, \ldots, S \) of i.i.d. draws in a joint distribution that defines, through known transformations, the joint distribution of the variables at stake to compute the expectation in (11). It is worth noting that, the missing data problem requires us to draw the simulated sample in a specific way: namely, because of the missing data, we can not simulate \( Y_{is}(\theta) \) when \( D_i = 0 \).

However, while we have maintained the standard assumption that the draws of stochastic errors \( \{\tilde{\varepsilon}_{is}\}_{i=1}^N \) are independent of \( \{\varepsilon_i, Z_i, X_i, D_i\}_{i=1}^N \), these draws are also independent of the missing data mechanism encapsulated in the variables \( \{D_i\}_{i=1}^N \). Therefore, the missingness indicator \( \{D_i\}_{i=1}^N \) are endowed with an exogeneity status in regards to the simulated errors. In particular, because \( D_i \) is independent of \( \tilde{\varepsilon}_{is} \), for each \( s = 1, \ldots, S \), given \( (\varepsilon_i, Z_i, X_i) \) since \( \tilde{\varepsilon}_{is} \) jointly independent of \( (\varepsilon_i, Z_i, X_i, D_i) \), we have that

\[
D_i \perp Y_{is}(\theta) \mid W_i, X_i. \tag{12}
\]

The conditional independence \( D \perp Y(\theta) \mid W, X \) generated through the simulation step is the key condition for validity of (11) since

\[
E \left[ \frac{D}{p_0(W)} m(Y(\theta), Z, X, \beta) \right] = E \left[ E \left[ \frac{D}{p_0(W)} m(Y(\theta), Z, X, \beta) \mid W, X \right] \right] \quad \text{(by L.I.E.)}
\]

\[
= E \left[ E \left[ \frac{D}{p_0(W)} \mid W, X \right] E \left[ m(Y(\theta), Z, X, \beta) \mid W, X \right] \right] \quad \text{(by (12))}
\]

\[
= E \left[ E \left[ \frac{D}{p_0(W)} \mid W \right] E \left[ m(Y(\theta), Z, X, \beta) \mid W \right] \right] \quad \text{(by MAR-X)}
\]

\[
= E \left[ m(Y(\theta), Z, X, \beta) \right] \quad \text{(by definition of } p_0(W) \text{)}. \quad \tag{13}
\]

It is crucial to point out that independence between \( \tilde{\varepsilon} \) and \( (\varepsilon, Z, X) \), as in a standard II context, is not sufficient to ensure equation (13). Moreover, equation (13) is precisely what we need to ensure an II approach that is feasible and valid, when based on the auxiliary model (1), in spite of the missing data problem.

\footnote{Alternatively, one can draw a single simulated sample of errors of size \( S \cdot N \).}
More precisely, for $\beta^0 \in B$ and $\theta \mapsto \beta^0(\theta)$ defined by, respectively,
\[
E \left[ m(Y, Z, X, \beta^0) \right] = 0,
E \left[ m(Y(\theta), Z, X, \beta^0(\theta)) \right] = 0,
\]
under the standard identification assumption $\beta^0 = \beta^0(\theta) \Leftrightarrow \theta = \theta^0$ comparison of (10) and (11) ensures that we can make this II approach feasible in spite of the missing data by solving the “observed” estimating equations
\[
E \left[ \frac{D}{p_0(W)} m(Y, Z, X, \beta^0) \right] = 0 \tag{14}
E \left[ \frac{D}{p_0(W)} m(Y(\theta), Z, X, \beta^0(\theta)) \right] = 0. \tag{15}
\]
This is where the novelty of our approach lies. Identification of $\theta^0$, by means of (10) and (13), does not result directly from the use of IPW under only MAR-X in (2) but also requires the conditional independence introduced through the simulation step.

Clearly, implementation of the above strategy requires consistent estimation of $p_0(W)$. The complete asymptotic theory will be developed in Section three in the framework of a fully parametric model. This parametric model will define the set of possible DGPs according to steps (O1), (O2), (O3) and (O4) above, augmenting it by a parametric specification $p(W; \gamma)$ for $\Pr[D = 1|W]$ in step (O4) such that
\[
p_0(W) = \Pr[D = 1|W] \equiv p(W; \gamma^0) \tag{16}
\]
for a unique $\gamma^0 \in \text{Interior}(\Gamma) \subset \mathbb{R}^{d_\gamma}$.

The reader familiar with nonparametric estimation of optimal instruments knows that an alternative solution to use estimating equations like (14)-(15) would be to come up with a consistent, albeit nonparametric, estimator of $p_0(W)$ (for example, by letting $d_\gamma \to \infty$). However, in the context of IPW, this would pave the way for new discussions about efficient II with missing data: Chen et al. (2008) (see also Graham (2011) and Chaudhuri et al. (2015)) show that a nonparametric estimator of $p_0(W)$ would actually lead, in general, to a more accurate estimator of $\beta^0$. This apparent paradox is easy to explain when one realizes that step (O4) provides a set of conditional moment restrictions
\[
E[D - p_0(W)|W] = 0. \tag{17}
\]
These conditional moment restrictions would in general bring relevant information about the unknown parameter $\beta$ beyond what can be brought by a given parametric model like (16). It must be kept in mind that parametric maximum likelihood estimation of such a parametric model amounts to picking a subset (of dimension $d_\gamma$) of the above conditional moment restrictions,
\[
E \left[ \frac{D - p_0(W)}{p_0(W)(1 - p_0(W))} \frac{\partial}{\partial \gamma} p(W; \gamma^0) \right] = 0
\]
that is optimal for estimation of $\gamma^0$. However, this set of moment restrictions does not exhaust all the information in (17) that could be relevant for the optimal estimation of $\beta^0$. While our focus of interest in this paper is not efficient direct estimation of $\beta$ but indirect estimation of $\theta$, obviously, the two efficiency issues are tightly related but much beyond the scope of this paper.

3 IPW Indirect Inference (IPW-II)

In this section we discuss precise implementation of our inverse probability weighted II (IPW-II) approach under MAR-X missing data. Asymptotic properties of the ensuing IPW-II approach are discussed in Section 3.4. Section 3.5 presents a computationally friendly implementation of this approach for non-smooth problems and presents subsequent asymptotic theory.

3.1 Estimation of the Auxiliary Model Parameters

3.1.1 Observed Data

Following the identification strategy devised in Section two, define the estimator $\hat{\beta}_N$ as the solution of

$$
\frac{1}{N} \sum_{i=1}^{N} \frac{D_i}{p(W_i, \hat{\gamma}_N)} m(Y_i, Z_i, X_i, \hat{\beta}_N) = 0,
$$

where $\hat{\gamma}_N$ is the maximum likelihood estimator, the solution to $0 = \sum_{i=1}^{N} l_\gamma(D_i, W_i, \gamma)$, with $l_\gamma(D_i, W_i, \hat{\gamma}_N)$ the score vector of the parametric model describing the missing data mechanism:

$$
l_\gamma(D_i, W_i, \gamma) = \frac{\partial}{\partial \gamma} \log \left( (p(W_i, \gamma))^{D_i} (1 - p(W_i, \gamma))^{1-D_i} \right)
= \frac{1}{p(W_i, \gamma)(1 - p(W_i, \gamma))} \frac{\partial p(W_i, \gamma)}{\partial \gamma} [D_i - p(W_i, \gamma)] = l_i,\gamma(\gamma). \quad (18)
$$

Note that $(\hat{\beta}_N', \hat{\gamma}_N')'$ can also be seen as a joint GMM estimator provided by the just identified moment conditions

$$
E \left[ \frac{D_i}{p(W_i; \gamma)} m(Y_i, Z_i, X_i, \beta) \right] = 0
E [l_\gamma(D_i, W_i, \gamma)] = 0
$$

It is well known (see, e.g., Breusch et al. (1999), Lemma 1, p93) that we can obtain an asymptotically equivalent GMM estimator by considering instead the moment conditions:

$$
E \left[ m_i^*(\gamma, \beta) - E \left[ m_i^*(\gamma^0, \beta^0) \mid l_i,\gamma(\gamma) \right] \right] = 0
E [l_\gamma(D_i, W_i, \gamma)] = 0 \quad (19)
$$

10
The following remarks are in order.

and, for \( \gamma = \gamma^0 \), \( \Pi [m_i^*(\gamma^0, \beta^0) \mid l_{i,\gamma}(\gamma)] \) is the affine regression of \( m_i^*(\gamma^0, \beta^0) \) on \( l_{i,\gamma}(\gamma) \); i.e.,

\[
\Pi [m_i^*(\gamma^0, \beta^0) \mid l_{i,\gamma}(\gamma)] = \Omega_{12} (\Omega_{22})^{-1} l_{i,\gamma}(\gamma),
\]

\[
\Omega_{12} = \text{Cov} [m_i^*(\gamma^0, \beta^0), l_{i,\gamma}(\gamma)], \quad \Omega_{22} = \text{Var} [l_{i,\gamma}(\gamma)].
\]

Clearly, the two moments in (19) are uncorrelated at the true value \((\gamma^0, \beta^0)\), allowing us to compute directly the asymptotic distribution of the GMM estimator \( \hat{\beta}_N \) from its asymptotic expansion\(^3\)

\[
\sqrt{N} (\hat{\beta}_N - \beta^0) = - [G'_0 V_0^{-1} G_0]^{-1} G'_0 V_0^{-1} \frac{1}{\sqrt{N}} \sum_{i=1}^{N} \{m_i^*(\gamma^0, \beta^0) - \Pi [m_i^*(\gamma^0, \beta^0) \mid l_{i,\gamma}(\gamma)]\} + o_P(1)
\]

\[
= - G_0^{-1} \frac{1}{\sqrt{N}} \sum_{i=1}^{N} \{m_i^*(\gamma^0, \beta^0) - \Pi [m_i^*(\gamma^0, \beta^0) \mid l_{i,\gamma}(\gamma)]\} + o_P(1),
\]

where

\[
G_0 = E \left[ \frac{D_i}{p(W_i; \gamma^0)} \frac{\partial m(W_i, X_i, \beta^0)}{\partial \beta'} \right],
\]

\[
V_0 = \text{Var} [m_i^*(\gamma^0, \beta^0)] - \text{Var} [\Pi [m_i^*(\gamma^0, \beta^0) \mid l_{i,\gamma}(\gamma)]]
\]

(21)

The following remarks are in order.

**Remarks:**

1. Applying again the MAR-X property to \( G_0 \) yields

\[
G_0 = E \left[ E \left[ \frac{D_i}{p(W_i; \gamma^0)} W_i, X_i \right] \frac{\partial m(W_i, X_i, \beta^0)}{\partial \beta'} \right] = E \left[ \frac{\partial m(W_i, X_i, \beta^0)}{\partial \beta'} \right],
\]

as if we had no missing data. However, due to the missing data problem, the formula (20) provides the natural way to estimate \( G_0 \) from its sample counterpart after plugging in a consistent estimator of \((\gamma^0, \beta^0)\). Similarly,

\[
\text{Var} [m_i^*(\gamma^0, \beta^0)] = E \left[ m_i^*(\gamma^0, \beta^0) m_i^*(\gamma^0, \beta^0)' \right] = E \left[ \frac{1}{p(W_i; \gamma^0)} m_i(\beta^0) m_i'(\beta^0) \right]
\]

should rather be estimated from the sample counterpart of (21) rather than the above equation. However, the division by \( p(W_i; \gamma^0) \) in the above equation shows the price we pay, in terms of accuracy of the GMM estimator of \( \beta \), for the missing data problem.

\(^3\)Precise regularity conditions ensuring the validity of this expansions are given as Assumptions A1-A5 in the appendix.
(2) The asymptotic variance of $\sqrt{N} (\hat{\beta}_N - \beta^0)$, given by $G_0^{-1} V_0 G_0^{-1}$, is smaller (in terms of comparison of positive semi-definite matrices) than the asymptotic variance of a GMM estimator that one would obtain if they knew the true unknown propensity score $p_0(W) = p(W; \gamma^0)$ and instead estimated $\beta^0$ using only

$$E \left[ \frac{D_i}{p_0(W_i)} m_i(Y, Z, X, \beta) \right] = 0,$$

for which the resulting asymptotic variance would be given by $G_0^{-1} \text{Var} [m_i^*(\gamma^0, \beta^0)] G_0^{-1}$.

This remark is sometimes summarized by a kind of puzzling statement: “it is better to estimate the weights by a conditional MLE procedure than using known weights (if we knew them)” (Wooldridge, 2007). The explanation of this anomalous statement is simple: we took advantage of the second set of moment conditions (provided by the score vector $l_{i, \gamma}(\gamma^0)$) by computing the residual of its regression on the second set. The possible efficiency loss when going to GMM based only on (22) instead of GMM estimator $\hat{\beta}_N$ based on the complete set is not due to the knowledge of $\gamma^0$ but to the possible omission of the second set of moment conditions $l_{i, \gamma}(\gamma^0)$, even when we don’t need to estimate $\gamma^0$.

### 3.1.2 Simulated Data

For a given integer $S \geq 1$, we can draw $S$ independently simulated samples of i.i.d. errors $\{\tilde{\varepsilon}_{is}\}_{i=1}^N$ from the known probability distribution of $\varepsilon$ with, for each $s = 1, ..., S$, $\{\tilde{\varepsilon}_{is}\}_{i=1}^N$ independent of $\{\varepsilon_i, Z_i, X_i, D_i\}_{i=1}^N$. We can then compute

$$Y_{is}(\theta) = r(Z_i, X_i, \tilde{\varepsilon}_{is}; \theta)$$

and define the estimator $\hat{\beta}_N^{(s)}(\theta)$ as the solution of

$$\sum_{i=1}^N \frac{D_i}{p(W_i; \tilde{\gamma}_N)} m \left( Y_{is}(\theta), Z_i, X_i, \hat{\beta}_N^{(s)}(\theta) \right) = 0.$$

Using similar arguments to those developed in the previous section, when $N$ is large,

$$\sqrt{N} \left( \hat{\beta}_N^{(s)}(\theta^0) - \beta^0 \right) = -G_0^{-1} \frac{1}{\sqrt{N}} \sum_{i=1}^N \left\{ m_i^*(\gamma^0, \beta^0; \theta^0) - \Pi \left[ m_i^*(\gamma^0, \beta^0; \theta^0) \mid l_{i, \gamma}(\gamma^0) \right] \right\} + o_P(1),$$

where $m_i^*(\gamma, \beta; \theta) = \frac{D_i}{p(W_i; \gamma)} m(Y_{is}(\theta), Z_i, X_i, \beta)$,

$$\Pi \left[ m_i^*(\gamma^0, \beta^0; \theta) \mid l_{i, \gamma}(\gamma) \right] = \Omega_{12}(\theta) (\Omega_{22})^{-1} l_{i, \gamma}(\gamma),$$

$$\Omega_{12}(\theta) = \text{Cov} \left[ m_i^*(\gamma^0, \beta^0; \theta), l_{i, \gamma}(\gamma^0) \right]$$

Note that $\Omega_{12}(\theta)$ does not depend on $(i, s)$ since all the draws $(Z_i, X_i, \tilde{\varepsilon}_{is})$ are drawn in the
same distribution. However, it is critical to note that,
\[ \Omega_{12}(\theta^0) \neq \Omega_{12}, \]
which follows from the fact that, for \( D(\varepsilon, Z_i, X_i, D_i) \) denoting the joint probability distribution of \((\varepsilon, Z_i, X_i, D_i)\), in general
\[ D(\varepsilon, Z_i, X_i, D_i) \neq D(\tilde{\varepsilon}, Z_i, X_i, D_i). \]

This discrepancy is a consequence of the missingness indicator \( D_i \) being endowed with an exogeneity status with regards to the simulated errors \( \tilde{\varepsilon} \), since \( \tilde{\varepsilon} \) is, by construction, independent of \((Z_i, X_i, D_i)\). In contrast to \( \tilde{\varepsilon} \), MAR-X does not require that the error \( \varepsilon \) be independent of \((Z_i, X_i, D_i)\) since \( D_i \) to be independent of \( Y_i \) given \((Z_i, X_i)\).

Following the first II estimator of Gourieroux et al. (1993) (see their proposition 1 pS89), an estimator of \( \theta \) can be obtained by calibrating the value of \( \theta \) in order to have the estimator \( \hat{\beta}_{N,S}(\theta) \) of auxiliary parameters close to the average value \( \hat{\beta}_{N,S}(\theta) = \frac{1}{S} \sum_{s=1}^{S} \tilde{\beta}_{N,s}(\theta) \).

From \( \hat{\beta}_{N,S}(\theta) \) and (23), we deduce that, for given \( S \),
\[ \sqrt{N} \left( \hat{\beta}_{N,S}(0) - \beta^0 \right) = -G_0^{-1} \frac{\sqrt{N}}{N} \sum_{i=1}^{N} \sum_{s=1}^{S} \left\{ m^*_s(\gamma^0, \beta^0; \theta^0) - \Pi [m^*_s(\gamma^0, \beta^0; \theta^0) \mid l_i, (\gamma^0)] \right\} + o_P(1). \]

### 3.2 The Calibration Step

Given auxiliary parameters estimates \( \hat{\beta}_N, \hat{\beta}_{N,S}(\theta) \), an efficient Wald-type IPW-II estimator for \( \theta \) is obtained as
\[ \hat{\theta}_N(\Upsilon) := \arg \min_{\theta \in \Theta} \left[ \hat{\beta}_N - \hat{\beta}_{N,S}(\theta) \right]' \Upsilon_N^{-1}(S) \left[ \hat{\beta}_N - \hat{\beta}_{N,S}(\theta) \right], \]
where \( \Upsilon_N \) is a positive definite weighting matrix that consistently estimates
\[ \Upsilon(S) := \lim_{N \to \infty} \text{Var} \left\{ \sqrt{N} \left( \hat{\beta}_N - \hat{\beta}_{N,S}(0) \right) \right\}. \]

To deduce the form of \( \Upsilon(S) \), we first use the expansions \( \sqrt{N}(\hat{\beta}_N - \beta^0) \) and \( \sqrt{N}(\hat{\beta}_{N,S}(\theta^0) - \beta^0) \), given in the previous subsections, to find
\[ \sqrt{N} \left( \hat{\beta}_N - \hat{\beta}_{N,S}(\theta^0) \right) = -G_0^{-1} \sqrt{N} \left[ \tilde{\xi}_{N,S} - C_0 \Omega_{22}^{-1} \sum_{i=1}^{N} l_{i,\gamma}(\gamma^0)/N \right] + o_P(1), \]
where \( C_0 = [\Omega_{12} - \Omega_{12}(\theta^0)] \) and

\[
\tilde{\xi}_{N,S} = \sum_{i=1}^{N} \xi_{i,S} / N \equiv \frac{1}{N} \sum_{i=1}^{N} \left[ m_i^* (\gamma^0, \beta^0) - \frac{1}{S} \sum_{s=1}^{S} m_{is}^* (\gamma^0, \beta^0; \theta^0) \right].
\]

Noting that,

\[
\text{Cov} \left( \sqrt{N} \tilde{\xi}_{N,S} , C_0 \Omega_{22}^{-1} \sum_{i=1}^{N} l_{i,\gamma}(\gamma^0) / \sqrt{N} \right) = C_0 \Omega_{22}^{-1} C_0' = \text{Var} \left( C_0 \Omega_{22}^{-1} \sum_{i=1}^{N} l_{i,\gamma}(\gamma^0) / \sqrt{N} \right)
\]

and for \( W_0(S) = \lim_{N \to \infty} \text{Var} \left\{ \sqrt{N} \tilde{\xi}_{N,S} \right\} = E \left[ \xi_{i,S} \cdot \xi_{i,S}' \right], \) \( \Upsilon(S) \) then has the following form:

\[
\Upsilon(S) = G_0^{-1} \left[ W_0(S) - C_0 \Omega_{22}^{-1} C_0' \right] G_0^{-1}.
\]

We have the following remarks about the components of \( \Upsilon(S). \)

**Remarks:**

(1) The term \( W_0(S) \) in \( \Upsilon(S) \) can further be decomposed by noting the following: one,

\[
\text{Var} \left[ m_{is}^* (\gamma^0, \beta^0; \theta^0) \right] = E \left[ \frac{D_i}{p^2 (W_i; \gamma^0)} m(Y_{is}(\theta^0), Z_i, X_i, \beta^0) m'(Y_{is}(\theta^0), Z_i, X_i, \beta^0) \right] = E \left[ \frac{1}{p(W_i; \gamma^0)} m(Y_{is}(\theta^0), Z_i, X_i, \beta^0) m'(Y_{is}(\theta^0), Z_i, X_i, \beta^0) \right] = \text{Var} \left[ m_i^* (\gamma^0, \beta^0) \right],
\]

where the second equality comes from an argument similar to the one used to prove (13) and the third equality is implied by the fact that the joint distributions satisfy \( D(\varepsilon_i, Z_i, X_i) = D(\tilde{\varepsilon}_{is}, Z_i, X_i) \); two, by the same logic, for \( s, s' = 1, ..., S \)

\[
\text{Cov} \left[ m_i^* (\gamma^0, \beta^0), m_{is'}^* (\gamma^0, \beta^0; \theta^0) \right] = \text{Cov} \left[ m_{is}^* (\gamma^0, \beta^0; \theta^0), m_{is'}^* (\gamma^0, \beta^0; \theta^0) \right].
\]

Introducing the notations,

\[
I_0 = \text{Var} \left[ m_i^* (\gamma^0, \beta^0) \right],
\]

\[
K_0 = \text{Cov} \left[ m_i^* (\gamma^0, \beta^0), m_{is}^* (\gamma^0, \beta^0; \theta^0) \right],
\]

elementary algebra yields

\[
W_0(S) = \left( 1 + \frac{1}{S} \right) (I_0 - K_0),
\]

which is similar to the result obtained in Gourieroux et al. (1993) (see the last formula pS109).

---

\(^4\)The term \( K_0 \) is non-zero in general because the observed and simulated samples both contain the common the exogenous variables \( X \) and \( Z \).
(2) The term $K_0$ can be further decomposed, by noting that, for $s, s' = 1, ..., S$, even if $s = s'$,

\[
K_0 = \text{Cov} \left\{ E[m_{i*}^s(\gamma^0, \beta^0; \theta^0) | Z_i, D_i X_i], E[m_{i*}^{s'}(\gamma^0, \beta^0; \theta^0) | Z_i, D_i X_i] \right\} \\
= \text{Var} \left\{ E[m_{i*}^s(\gamma^0, \beta^0; \theta^0) | Z_i, D_i X_i] \right\} = \text{Var} \left\{ E[m_{i}^s(\gamma^0, \beta^0) | Z_i, D_i X_i, D_i] \right\}
\]

which yields following alternative specification for $I_0 - K_0$:

\[
I_0 - K_0 = \text{Var} \left\{ m_{i*}^s(\gamma^0, \beta^0) - E[m_{i*}^s(\gamma^0, \beta^0) | Z_i, D_i X_i, D_i] \right\}.
\]

This expression makes explicit the efficiency gain due to the fact that we do not simulate the exogenous variables.

### 3.3 Alternative Implementation: IPW-II Estimator

The Wald-type II estimator in equation (24) is computationally expensive in situations where $\hat{\beta}_{N,S}(\theta)$ is not known in closed form. For computational simplicity we can instead consider estimators of $\theta$ defined as, near, minimizers of

\[
\left\| M_{N,S}(\hat{\beta}_N, \hat{\gamma}_N, \theta) \right\|_{A_N},
\]

where $A_N$ is a given sequence of positive definite matrices (with positive definite probability limit $A$). Following Gourieroux et al. (1993) (see their formula page S91), it is well-known that with the appropriate choice of weighting matrix, an II estimator based on (24) is asymptotically equivalent to an II estimator based on (25). Note that our case is slightly more general than Gourieroux et al. (1993) since they consider only estimating equations for $\beta$ given by the score of an auxiliary model. Then, their matrix $G_0$ is the Hessian matrix and is symmetric and positive definite. The extension to our context is straightforward if $G_0$ is a non-singular matrix.

Exact implementation of the IPW-II approach can be carried out using the following algorithm, which deals with the potential non-smoothness, in $\theta$, of $\left\| M_{N,S}(\hat{\beta}_N, \hat{\gamma}_N, \theta) \right\|_{A_N}$.

**Algorithm for implementing of IPW-II**

- **Step 0:** Using the observed sample $\{W_i, D_i\}_{i=1}^N$ estimate $\hat{p}_0(W_i) := p(W_i; \hat{\gamma}_N)$ for each $i = 1, \ldots, N$ where $\hat{\gamma}_N$ is the maximum likelihood estimator based on any *given* parametric specification $p(W; \gamma)$ for $p_0(W)$, and where $\gamma$ is some $d_\gamma \times 1$ unknown parameter.

- **Step 1:** Using the observed sample $\{W_i, D_i, X_{i,\text{obs}} := D_i X_i\}_{i=1}^N$, obtain $\hat{\beta}_N$ as:

\[
\hat{\beta}_N := \arg_{\beta \in B} \{ M_N(\beta, \hat{\gamma}_N) = 0 \}
\]

where

\[
M_N(\beta, \gamma) := \frac{1}{N} \sum_{i=1}^N \frac{D_i}{p(W_i; \gamma)} m(Y_i, Z_i, X_{i,\text{obs}}, \beta).
\]

---

5Such situations arise in simulation based estimation of discrete choice models because the simulated dependent variable, as a function of $\theta$, i.e., $Y(\theta)$, can change discretely (e.g. from 0 to 1) with an infinitesimal change in $\theta$. 

15
• **Step 2a:** Sort the observed sample so that the first \( N_1 = \sum_{i=1}^{N} D_i \) units have \( D_i = 1 \), i.e., have \( X_i \) observed. For any given \( \theta \in \Theta \), and for each \( i = 1, \ldots, N_1 \), generate:

\[
\varepsilon_{is} \sim F_\varepsilon^0, \quad Y_{is}(\theta) = r(Z_i, X_i, \theta, \varepsilon_{is}) \quad \text{for} \quad s = 1, \ldots, S
\]

where \( S \) is the pre-specified number of simulations. Set \( Y_{is}(\theta) = 0 \) for \( s = 1, \ldots, S \) and \( i = N_1 + 1, \ldots, N \). (This is inconsequential because we will not use these remaining \( i \)'s.)

• **Step 2b:** For any given positive definite matrix \( A_N \), obtain the II estimator \( \hat{\theta}_N(A_N) \) as:

\[
\| M_{N,S} \left( \hat{\beta}_N, \hat{\gamma}_N, \hat{\theta}_N(A_N) \right) \|_{A_N} \leq o_P \left( N^{-1/2} \right) + \inf_{\theta \in \Theta} \| M_{N,S} \left( \hat{\beta}_N, \hat{\gamma}_N, \theta \right) \|_{A_N}
\]

(26)

where \( M_{N,S}(\beta, \gamma, \theta) := \frac{1}{NS} \sum_{i=1}^{N} \frac{D_i}{p(W_i; \gamma)} \sum_{s=1}^{S} m(Y_{is}(\theta), Z_i, X_i^{\text{obs}}, \beta) \).

We call \( \hat{\theta}_N(A_N) \) the IPW-II estimator of \( \theta^0 \).

**Remarks:**

1. The IPW-II procedure models \( p_0(W) \) parametrically and is susceptible to misspecification. Adverse consequences of parametric misspecification of \( p_0(W) \) in Step 0, and remedy thereof by using doubly robust estimating functions for \( \beta \) or by nonparametric estimation of \( p_0(W) \) have been studied for general IPW estimators [e.g., Scharfstein et al. (1999), Hirano et al. (2003), Chen et al. (2008)].

2. Optimal choice of \( A = \text{plim}A_N \) follows from Gourieroux et al. (1993) with an additional modification due to the fact that the nuisance parameter \( p_0(W) \) is estimated. Even with the optimal \( A \), the relative efficiency of the II estimator of \( \theta \) with respect to the full information maximum likelihood estimator ultimately depends on the “richness” of the auxiliary model. Keane and Smith (2005) provide an illuminating demonstration with simulations.

### 3.4 Asymptotic Distribution of the IPW-II Estimator

We provide precise results for consistency and asymptotic normality of the IPW-II estimator. For the sake of generality, we deviate from the standard II treatment (see Gourieroux et al. (1993)) and present results that accommodate for non-smoothness with respect to \( \theta \) in the moment vector \( m(Y(\theta), Z, X, \beta) \). The required technical assumptions \( \text{A1-A7} \), along with the proofs of the stated results, which are similar in spirit to and based on Pakes and Pollard (1989), are collected in the Appendix.

**Proposition 1.** Let \( \text{A1-A6}(1) \) in the Appendix hold. Let \( S \) be fixed and \( A_N \xrightarrow{P} A \) as \( N \to \infty \) where \( A \) is positive definite. Then the IPW-II estimator in (26) satisfies: \( \hat{\theta}_N(A_N) \xrightarrow{P} \theta^0 \).

**Proposition 2.** Let Assumptions \( \text{A1-A7} \) in the Appendix hold. Let \( S \) be fixed and \( A_N \xrightarrow{P} A \) as \( N \to \infty \) where \( A \) is symmetric and positive definite. Let \( \frac{\partial}{\partial \theta} \beta^0(\theta^0) \) be full column rank. Then the
IPW-II estimator in (26) satisfies: $\sqrt{N}(\hat{\theta}_N(A) - \theta^0) \xrightarrow{d} N(0, \Sigma(A))$ where:

$$
\Sigma(A) := \left[ \frac{\partial \beta^0(\theta^0)'}{\partial \theta} G'_0 A G_0 \frac{\partial \beta^0(\theta^0)}{\partial \theta'} \right]^{-1} \frac{\partial \beta^0(\theta^0)'}{\partial \theta} G'_0 A H_0 A G_0 \frac{\partial \beta^0(\theta^0)}{\partial \theta'} \left[ \frac{\partial \beta^0(\theta^0)'}{\partial \theta} G'_0 A G_0 \frac{\partial \beta^0(\theta^0)}{\partial \theta'} \right]^{-1},
$$

$$
G_0 := E \left[ \frac{\partial}{\partial \beta^0} m(Y, Z, X, \beta^0) \right] = E \left[ \frac{\partial}{\partial \beta^0} m(Y(\theta^0), Z, X, \beta^0) \right],
$$

$$
H_0 := W_0(S) - C_0 \Omega_{22}^{-1} C_0' \equiv \left( 1 + \frac{1}{S} \right) [I_0 - K_0] - C_0 \Omega_{22}^{-1} C_0',
$$

$$
C_0 := \Omega_{12} - \Omega_{12}(\theta^0) \equiv E \left[ \frac{D}{p_0(W)} \left\{ m(Y, Z, X, \beta^0) - m(Y(\theta^0), Z, X, \beta^0) \right\} \frac{\partial}{\partial \gamma} p(W; \gamma^0) \right].
$$

Remarks:

1. The optimal $A$ is $A_{opt} = H_0^{-1}$. Hence the optimal asymptotic variance given the auxiliary model is: $\Sigma(A_{opt}) = \left[ \frac{\partial \beta^0(\theta^0)'}{\partial \theta} G'_0 H_0^{-1} G_0 \frac{\partial \beta^0(\theta^0)}{\partial \theta'} \right]^{-1}$. The missing $X$ and the estimation of the nuisance parameters $\gamma$ to model this missingness make this optimal asymptotic variance different from that given in Proposition 4 of Gourieroux et al. (1993). Without the former, $W_0(S)$ would reduce to standard definitions given in Gourieroux et al. (1993); i.e., $\xi_i$, defining the asymptotic expansion of $\sqrt{N}\left(\hat{\beta}_N - \hat{\beta}_{N,S}(\theta^0)\right)$, would reduce to $m(Y_i, Z_i, X_i, \beta^0) - \frac{1}{S} \sum_{s=1}^{S} m(Y_{i,s}(\theta^0), Z_i, X_i, \beta^0)$. Without the latter, $C_0 \Omega_{22}^{-1} C_0'$ would not appear in the definition of $H_0$. And the difference between the two formulas would disappear.

2. The matrix $H_0$ can be equivalent written in the more compact form

$$
H_0 := E \left[ (\xi_i - \Pi(\xi_i | l_\gamma(D_i, W_i; \gamma^0))) (\xi_i - \Pi(\xi_i | l_\gamma(D_i, W_i; \gamma^0)))' \right],
$$

$$
\xi_i := \frac{D_i}{p_0(W_i)} \left\{ m(Y_i, Z_i, X_i, \beta^0) - \frac{1}{S} \sum_{s=1}^{S} m(Y_{i,s}(\theta^0), Z_i, X_i, \beta^0) \right\},
$$

where $l_{i,\gamma}(\gamma)$ was defined in (18), and $\Pi(\xi_i | l_{i,\gamma}(\gamma^0))$, stands for the affine regression of $\xi_i$ on $l_{i,\gamma}(\gamma^0)$. Using this formula the asymptotic variance of the IPW-II estimator can be stated as

$$
\Sigma(H_0^{-1}) = \left[ \frac{\partial \beta^0(\theta^0)'}{\partial \theta} G'_0 \left\{ E \left[ (\xi_i - \Pi(\xi_i | l_\gamma(D_i, W_i; \gamma^0))) (\xi_i - \Pi(\xi_i | l_\gamma(D_i, W_i; \gamma^0)))' \right] \right\} \right]^{-1} G'_0 \frac{\partial \beta^0(\theta^0)}{\partial \theta'} G_0 \left[ \frac{\partial \beta^0(\theta^0)'}{\partial \theta} G'_0 A H_0 A G_0 \frac{\partial \beta^0(\theta^0)}{\partial \theta'} \right]^{-1}.
$$

The above formula is similar to existing formulas describing the asymptotic variance covariance of GMM estimators with missing data, see, e.g.,

3. The IPW-II estimator is based on inverse probability weighting the so called complete cases, i.e., sample units with no missing variables, to correct for the endogenous missingness/selection. This makes it widely applicable to scenarios where the pattern of missingness is more complex [see Little and Rubin (2002)]. For example, let $X = (X_1', X_2')'$ and suppose we observe $(Y', Z')$ for some sample units, $(Y', Z', X_1')'$ for some and $(Y', Z', X')'$ for the rest. This is a scenario of monotonic pattern in missingness. If there is another subset of the sample units where we observe $(Y', Z', X_2')'$, then this is a scenario of non-monotonic pattern in missing-
ness. The above algorithm can be directly applied under both scenarios since it works with the complete cases only, i.e., sample units for which we observe \((Y', Z', X')'\). However, the estimator will not be semiparametrically efficient in the sense of Robins et al. (1994) and Robins and Rotnitzky (1995).

Since the driving force behind the potential loss in efficiency related to Remarks (2) and (3) above are well understood now, we abstract from such efficiency considerations to keep this paper short.

### 3.5 Smoothed Implementation: IPW-GII Estimator

Implementation of the IPW-II estimator when \(M_{N,S}(\beta, \gamma, \theta)\) is non-smooth in \(\theta\) can be computationally burdensome. Following Keane and Smith (2005), we propose an alternative estimator that simplifies estimation via smoothing. The smoothed estimator is obtained in the same manner as \(\hat{\theta}_{N}\), except that \(Y_{is}(\theta)\) in the original algorithm is replaced by a transformation \(Y_{is}(\theta, h_{N})\) that is smooth (continuously differentiable) in \(\theta\) for \(h_{N} > 0\), where

\[
\lim_{h_{N} \to 0} Y_{is}(\theta, h_{N}) = Y_{is}(\theta) \quad \text{for all } s = 1, \ldots, S \text{ and } i = 1, \ldots, N. \tag{27}
\]

The term \(h_{N}\) controls the smoothness of the transformation – larger (smaller) \(h_{N}\) leads to a more (less) smooth transformation but increases (decreases) estimation bias – and needs to be specified by the user taking into consideration the sample size \(N\) and the simulation size \(S\).

Such transformations are widely used in simulation-based estimation of discrete choice models to avoid computational difficulties arising from the non-differentiability of the concerned estimating equations with respect to \(\theta\) (see Train, 2009). To our knowledge, Keane and Smith (2005) were first to propose its use in the context of II. They named the ensuing II procedure Generalized Indirect Inference (GII). Bruins et al. (2015) present a thorough theoretical exposition of GII.

We formally define the GII (smoothed) estimator \(\tilde{\theta}_{N}^{h}(A_{N})\) as a solution of:

\[
\left\| M_{N,S}^{h}(\hat{\beta}_{N}, \hat{\gamma}_{N}, \tilde{\theta}_{N}^{h}(A_{N})) \right\|_{A_{N}} \leq o_{P}(N^{-1/2}) + \inf_{\theta \in \Theta} \left\| M_{N,S}(\hat{\beta}_{N}, \hat{\gamma}_{N}, \theta) \right\|_{A_{N}}, \tag{28}
\]

where \(M_{N,S}^{h}(\beta, \gamma, \theta) := \frac{1}{NS} \sum_{i=1}^{N} \frac{D_{i}}{p(W_{i}; \gamma)} \sum_{s=1}^{S} m(Y_{is}(\theta, h_{N}), Z_{i}, X_{i}^{obs}, \beta, \cdot)\) and refer to \(\tilde{\theta}_{N}^{h}(A_{N})\) as the IPW-GII estimator of \(\theta^{0}\).

The proposed smoothing approach in Keane and Smith (2005) is more sophisticated than (28) and involves choosing the appropriate smoothing parameter \(h\) in two steps, which is not fully reflected in the definition (28). In our Monte Carlo experiment involving estimation of structural parameters in a multinomial probit model, however, a naive one-step choice of \(h\) for the IPW-GII estimator provides significant improvements over the IPW-II estimator. In particular, not only does it reduce the computational cost substantially but it also improves the asymptotic normality approximation for the distribution of the II estimator.\(^6\)

Asymptotic equivalence between \(\tilde{\theta}_{N}^{h}(A_{N})\) and \(\hat{\theta}_{N}(A_{N})\) is ensured by letting \(h_{N} \to 0\) at a

\[^{6}\text{With minor modifications to the assumptions and the theoretical results presented in this paper one can also accommodate the two-step procedure for the choice of } h, \text{ if needed, following the results in Bruins et al (2015).}\]
controlled rate ($\sqrt{N} h_N = o(1)$) and under additional, but standard, technical conditions on the quantities depending on $h_N$. We collect these conditions under assumption A8 in the Appendix.

**Proposition 3.** Under Assumptions A1-A8 in the Appendix, for some sequence of non-negative real numbers $h = h_N$ satisfying $\sqrt{N} h_N = o(1)$,

$$\sqrt{N} \| \hat{\theta}_N(A) - \tilde{\theta}_N^h(A) \| = o_P(1).$$

4 Illustrative Example: Multinomial Probit Model

Herein, we consider a multinomial probit model similar to Section 9 in Gourieroux et al. (1993). However, our choice of the auxiliary model is different. It is based on (14)-(15), which leads to ordinary least squares computations, and has similarities with the auxiliary models in Keane and Smith (2005) and Li (2010), with Keane and Smith (2005) using this auxiliary model to estimate the parameters of the multinomial probit model. Section 4.1 specifies the auxiliary model for II and establishes the identification conditions A2 and A3 without explicit consideration of the missing variables. However, missing variables under MAR-X can be accommodated by simply replacing the moment vector for the auxiliary model by its inverse probability weighted version. The satisfaction of A2 and A3 ensure the adequacy of the auxiliary model for use in II. Section 4.2 presents a simulation study demonstrating the effectiveness in finite samples of the IPW-II and IPW-GII estimators in this model when the exogenous variable $X$ is missing endogenously following MAR in (2), i.e., MAR-X.

4.1 Indirect Inference: Multinomial Probit Model

Consider a ($J + 1$)-alternative multinomial probit model with the alternative 0 as the baseline:

$$Y = \sum_{j=1}^{J} j \times 1(U_j > \max(0, U_k : k = 1, \ldots, J \text{ and } k \neq j)),
$$

where $U_j = Z_j' \alpha + X' \lambda_j + e_j$,

and $(e_1, \ldots, e_k)' = \Omega^{1/2}(\varepsilon_1, \ldots, \varepsilon_k)'$ with $\Omega^{1/2}$ lower triangular such that $\Omega^{1/2} \Omega^{1/2}' = \Omega$.

Let $(\varepsilon_1, \ldots, \varepsilon_k)' \sim N(0, I_k)$ be independent of $Z = (Z_1', \ldots, Z_J')'$, i.e., say the alternative dependent variables, and $X$, i.e., say the purely individual specific variables.\(^7\) This corresponds to the structural model (8). Let the structural parameters be $\theta = (\alpha', h'_1, \ldots, h'_J, \omega')'$ where $\omega$ are the unique unrestricted elements of $\Omega$. $\theta = \theta^0$ in our population of interest.

Our implementation of II in this multinomial probit model follows the same steps described in Section 3.1-3.3. One possible choice for $m(.)$, which we follow in the Monte-Carlo experiment

\(^7\)Normality of $\varepsilon$ rules out ties in $U_j$’s almost surely in $Z$ and $X$. Also assume that the usual restrictions for identification, such as standardizing $\alpha$, $\lambda_j$’s and $\Omega$ with respect to the (1,1)-th element of $\Omega$, and/or any other context specific restrictions are imposed. We abstract from all such issues that are peripheral to the message of our paper.
in Section 4.2, is to take:

\[ m(R, Z, X, \beta) = \begin{bmatrix}
\text{vech} & \begin{pmatrix}
\zeta(R_1 - \zeta' \beta_1) \\
\vdots \\
\zeta(R_J - \zeta' \beta_J)
\end{pmatrix} \\
\begin{pmatrix}
R_1 - \zeta' \beta_1 \\
\vdots \\
R_J - \zeta' \beta_J
\end{pmatrix} & \begin{pmatrix}
\beta_{11} & \ldots & \beta_{1J} \\
\vdots & \ddots & \vdots \\
\beta_{1J} & \ldots & \beta_{JJ}
\end{pmatrix}
\end{bmatrix} \] (30)

where \( R \) (stands for response) is either \( Y \) or \( Y(\theta) \), as appropriate. \( R_j = 1(R = j) \) for \( j = 1, \ldots, J \) and \( \beta = (\beta_1', \ldots, \beta_J', \beta_{11}, \ldots, \beta_{1J}, \beta_{21}, \ldots, \beta_{JJ})' \). \( \zeta \) is some vector valued function of \( Z \) and \( X \); for example, \( \zeta = (1, Z', X')' \). A “richer” function \( \zeta \), for example, that also includes quadratic terms in \( Z \) and \( X \), increases the “richness” of the auxiliary model and generally leads to higher efficiency of II; see Keane and Smith (2005) for a careful demonstration.

This choice of \( m(.) \) has the benefit of only requiring simple computations of equation-by-equation ordinary least squares in a seemingly unrelated regression (SUR) model with \( J \) response variables \( 1(Y = j) \) or \( 1(Y(\theta) = j) \) for \( j = 1, \ldots, J \); same set of regressors \( \zeta \) for all regressions; and regression errors with unknown variance-covariance matrix. In particular, this choice of \( m(.) \) leads to the first order conditions (that are efficient given \( \zeta \)) for the SUR model regression coefficients, augmented by the estimating equations for the unique elements in the variance-covariance matrix of the SUR regression errors. Hence, for a given \( \zeta \), the computation and efficiency consideration involved with this choice of \( m(.) \) are the same as that due to the quasi maximum likelihood estimation of the parameters of the auxiliary model in Keane and Smith (2005).

Lemma 1 below shows that when no variables are missing, standard least squares identification conditions are sufficient for the key identification conditions \( \text{A2} \) and \( \text{A3} \) to hold in II based on the auxiliary model induced by the choice of \( m(.) \) in (30). The proof is trivial and hence omitted.

Lemma 1. Define \( Y_j := 1(Y = j) \) and \( Y_j(\theta) := 1(Y(\theta) = j) \). Then Assumption \( \text{A2} \) in the Appendix holds if \( E[\zeta \zeta'] \) is non-singular, while Assumption \( \text{A3} \) in the Appendix holds under the additional orthogonality restriction \( E[\zeta (Y_j(\theta) - Y_j(\theta^0))] = 0 \) or, equivalently, \( E[\zeta (Y_j(\theta) - Y_j)] = 0 \) for \( j = 1, \ldots, J \) if and only if \( \theta = \theta^0 \).

Remarks:

(1) The lemma also applies to other discrete response models as long as the non-singularity and orthogonality conditions hold. This does not contradict the well known results that, typically such orthogonality (or even mean independence) conditions are not sufficient for non-parametric identification of the structural parameters in discrete response models. While apparently no other distributional assumption has been made in its statement, the lemma is highly parametric and could not possibly be used without knowing the distribution of \( Y_j(\theta) \) conditional on \( Z, X \).

(2) Section 4.2 takes \( \zeta = (1, Z', X')' \) and, therefore, according to Lemma 1 it implicitly requires for identification of \( \theta^0 \) the following high level orthogonality conditions:

(a) \( P(Y_j(\theta) = 1) = P(Y_j(\theta^0) = 1) \) for all \( j = 1, \ldots, J \) if and only if \( \theta = \theta^0 \).
(b) $E[Z(P(Y_j(\theta) = 1|Z, X) - P(Y_j(\theta^0) = 1|Z, X))] = 0$ for all $j = 1, \ldots, J$ if and only if $\theta = \theta^0$.

(c) $E[X(P(Y_j(\theta) = 1|Z, X) - P(Y_j(\theta^0) = 1|Z, X))] = 0$ for all $j = 1, \ldots, J$ if and only if $\theta = \theta^0$.

(3) A “richer” $\zeta$, for example, that also includes quadratic terms in $Z$ and $X$, would impose additional such orthogonality conditions and thereby would lead to higher precision of the II estimates.

(4) The result directly applies to our framework of endogenously missing exogenous variables $X$ by replacing $m(R, Z, X, \beta)$ in (30) by $\frac{D}{D X m(R, Z, X, \beta)}$ and appealing to MAR-X.

Finally, Lemma 1 can also be used to identify the pseudo-true $\theta$ (call it $\theta^*$) estimated by II when the exogenous variables $X$ are missing endogenously following MAR in (2) and the missingness is simply ignored. Hereafter, we will refer to an II procedure that simply ignore the missingness as standard II.

Consider the following toy example where, for simplicity of demonstration, we take $J = 1$, ignore $Z$, and make specific and convenient distributional assumptions that are covered by the maintained assumptions.

**Toy Example:** Let the structural model and the missingness mechanism be characterized by:

$$Y = 1(X\lambda^0 + \epsilon \geq 0) \quad \text{and} \quad D = 1(Y\gamma^0 + v \geq 0)$$

where the scalar random variable $X$, the structural error $\epsilon$ and the missingness error $v$ are assumed to be independent. Let $\theta^0 = \lambda^0$. Following (30), define $m(R, X, \beta) = X(R - X\beta)$ for $R = Y$ or $R = Y(\theta)$. We ignore the overidentifying (second moment) restrictions from (30) for simplicity.

Therefore, using the observed data, standard II defines $\beta^0$ and $\beta^0(\theta)$ from (1) as follows:

$$\beta^0 \text{ solves } E[DXY(Y - X\beta)] = 0, \quad \text{and} \quad \beta^0(\theta) \text{ solves } E[DXY(Y(\theta) - X\beta)] = 0.$$

These are essentially the population version of the first two steps of standard II. The final step obtains $\theta^*$ by a matching exercise, such as, $\beta^0 = \beta^0(\theta^*)$ which, by Lemma 1, holds if and only if $E[DXY(\theta^*)] = E[DXY]$. Letting $F_T$ denote the distribution function of any variable $T$, we know:

$$E[DXY(\theta^*)] = E \left[ ((1 - F_\epsilon(-\gamma^0))(1 - F_\epsilon(-X\theta^0)) + (1 - F_\epsilon(0))F_\epsilon(-X\theta^0))F_\epsilon(-X\theta^*)X \right],$$

$$E[DXY] = E \left[ (1 - F_\epsilon(-\gamma^0))(1 - F_\epsilon(-X\theta^0))X \right].$$

The above equalities follow from using MAR-X in (2), the conditional (on $X$) independence between $Y$ and $Y(\theta)$, and the fact that $F_\epsilon = F_T$. For simplicity, assume the specific and convenient distributions: $\epsilon \sim N(0, 1), v \sim N(0, 1)$ and $X \sim \text{Bernoulli}(q)$. Denote the distribution function of $N(0, 1)$ by $\Phi(.)$ and its inverse by $\Phi^{-1}(.)$. Therefore, equating $E[DXY(\theta^*)] = E[DXY]$ we obtain, for standard II,

$$\text{(pseudo-true value)} \quad \theta^* = \Phi^{-1} \left( \frac{\Phi(\gamma^0)\Phi(\theta^0)}{\Phi(\gamma^0)\Phi(\theta^0) + \Phi(0)(1 - \Phi(\theta^0))} \right) \neq \theta^0 \quad \text{(true value)}$$

unless $\gamma^0 = 0$, i.e., unless the missingness is exogenous. Hence, it is the endogeneity of the
missingness that causes the problem of identification with standard II. Our proposed II solves this problem.

4.2 Simulation Study: Three Alternative \((J = 2)\) Probit Model

The simulation design considered here is similar to Model 4 in Keane and Smith (2005) and Bruins et al. (2015). In particular, we consider the multinomial probit model in (29) with \(J = 2\). For each \(i = 1, \ldots, N\), we generate the exogenous regressors as: \(Z_{ji} \sim \chi^2_1 - 1\) for \(j = 1, 2\) and \(X_i \sim N(1, 2)\) independent of each other. Normalizing all the parameters in the model by the \((1,1)\)-th element of \(\Omega\), i.e., equivalently, by fixing \(\omega_{11} = 1\) (not to be estimated), we take \(\theta^0 = (\alpha^0 = 1, \lambda^0 = 1, \lambda^0_2 = 2, \omega^0_{12} = .5, \omega^0_{22} = 1)\). We generate the structural errors \(e_i \sim N(0, I_2)\) and \(e_i = \Omega^{1/2} e_i\) independent of the regressors \(Z_{1i}, Z_{2i}, X_i\) and, finally, we generate the outcome \(Y_i\) following (29) for each \(i = 1, \ldots, N\).

We consider the following missingness mechanism that determines the observability of \(X\). Generate

\[
D_i = 1(\gamma^0_1 \times 1(Y_i = 1) + \gamma^0_2 \times 1(Y_i = 2) + \gamma^0_3 \times Z_{2i} \geq v_i)
\]

for each \(i = 1, \ldots, N\) with \(v_i \sim N(0, 1)\) independent of the structural errors \(e_i\) and the exogenous variables \(Z_i = (Z_{1i}, Z_{2i})'\) and \(X_i\). Hence MAR-X in (2) holds. Take \(\gamma^0_1 = -.5, \gamma^0_2 = .5\) and \(\gamma^0_3 = 1\). This leads to roughly 50% of sample units with missing \(X\).

We consider the auxiliary model and the corresponding auxiliary parameters as defined by (1) based on the choice of \(m(.)\) given in (30) with \(\zeta = (1, Z_1, Z_2, X)'\).

We consider four estimators: the standard II estimator, an infeasible II estimator, the IPW-II and IPW-GII estimators introduced in Section 3. The standard II estimator works with the complete case data \(\{D_iY_i, D_iZ_i, D_iX_i\}(i = 1, i.e., sample units without any missing variables. Standard II ignores the endogenous missingness of \(X\) and thus can be biased, gauging the magnitude and consequences of this bias is the first purpose of the simulation study. The infeasible II estimator works with the infeasible full data set \(\{Y_i, Z_i, X_i\}(i = 1, N\), which is only available because we have generated the data (and the subsequent missingness), and is not available in practice. The infeasible II is the II estimator that one would use if there were no missingness in the data. Its finite-sample behavior provides an infeasible benchmark for the performance of II in this context. The IPW-II and IPW-GII estimators work with the observed data \(\{D_iY_i, D_iZ_i, D_iX_i\}(i = 1, N\) but account for the endogeneity in the missingness of \(X\). These estimators are designed to correct the bias of the standard II estimator, and demonstrating this is the second purpose of the simulation study. The third purpose of the study is to demonstrate that the normal approximation in Proposition 2 may only be appropriate for the IPW-II estimator asymptotically, even when the sample size is very large. Lastly, the simulation study demonstrates that the IPW-GII estimator does not suffer from this issue thanks to the smoothing proposed by Keane and Smith (2005).

We compute the mean bias (MBIAS), mean absolute bias (ABIAS), standard deviation (STD), interquartile range (IQR) and the coverage of a 95% Wald-confidence interval (COV95) for all the estimators of \((\alpha^0, \lambda^0, \lambda^0_2, \omega^0_{12}, \omega^0_{22})\) for sample sizes \(N = 200, 500, 1000\) and 5000. We take \(S = 10\). The standard II, infeasible II and IPW-II estimators are computed by the patternsearch routine in Matlab. On the other hand, the smoothness of the optimization problem for the IPW-GII estimator allows the use of the gradient-based Matlab routine fminunc. Fol-
lowing Keane and Smith (2005), the initial value is set at the true parameter value for all four estimation procedures. All four estimators use the (estimator specific) optimal weighting matrix (see Proposition 3.2), and in effect are continuously updated generalized method of moments estimators. All results are based on 10,000 Monte-Carlo trials.

To abstract from biases due to small sample sizes and instead focus on the bias that arises because the standard II estimator deliberately ignores the endogenous missingness, we only report the results for the standard II estimator based on \( N = 5000 \) in Table 1. (Results for other sample sizes are available from the authors.) This estimator is badly biased (MBIAS). As a consequence, the coverage of the 95% confidence intervals for the unknown parameters are extremely low: indeed as low as 1%.

Table 2 reports the results for the other three estimators. As expected from the results in Section 3, the IPW-II corrects the bias of the standard II estimator. Its bias (MBIAS) decreases considerably as the sample size increases. ABIAS, STD and IQR also display similar pattern with the increase in sample size. The coverage (COV95) is good. Overall, keeping in mind that \( X \) is missing for roughly 50% sample units, the finite-sample behavior of the IPW-II estimator does not deviate much from that of the infeasible benchmark provided by the infeasible II estimator, especially when the sample size is not too low.

Similar phenomenon of bias correction is observed for the IPW-GII estimator. However, its bias (MBIAS) is larger than that of the IPW-II estimator. Its ABIAS, STD and IQR are also generally larger than that of the IPW-II estimator. These features are possibly due to the naive one-step choice for the smoothing parameter \( h_N \) in the implementation of the IPW-GII estimator.8

Nevertheless, the IPW-GII estimator indeed serves the dual purpose stated in Section 3. The IPW-GII estimator is much faster than the IPW-II estimator, and more importantly, while the studentized IPW-II estimator is far from from being normally distributed, even for large sample size \( N = 5000 \), no such problem arises for the IPW-GII estimator;9 Figure 1 gives precise details.

## 5 Conclusion

In this paper we have demonstrated the problems with identification and consistent estimation of the structural parameters by II when the exogenous variables can be endogenously missing. Under the MAR assumption, which may arise in empirical work for reasons such as survey non-response, survey revisions, cost-effective survey design, etc. Our proposed solution, which we call the modified method of II, can be implemented as either the IPW-II or the IPW-GII estimator. This novel estimation method corrects for the sample selection bias in the estimation of the auxiliary parameters with the observed data and the simulated data using the method

8The smoothing parameter \( h_N \) is .078, .0571, .0458, .0284 respectively for \( N = 200, 500, 1000, 5000 \). This is in rough accordance to the requirements of Proposition3 but with a slight tilt toward zero for the smaller sample sizes \( N = 200, 500 \) to reduce the bias due to smoothing.

9The same issue is also present in the infeasible II estimator. However, for both the infeasible II and IPW-II, the quality of the normal approximation is better if we use a richer auxiliary model by augmenting \( \zeta = (1, Z', X')' \) with quadratic terms in \( Z \) and \( X \). This removes some wigginess in the corresponding kernel density plots. These figures are not included for brevity but can be found in the previous version of the paper and are available from the authors.
of inverse probability weighting. The desirable performance of the proposed II approach was demonstrated theoretically and via simulations. The extremely poor performance of standard II based on simply discarding sample units with missingness was also demonstrated via simulations. Finally, we conclude by noting that in comparison with II based on discarding sample units with missingness, our proposed method involves only one additional preliminary step of estimation of a binary choice model such as logit or probit, and hence retains the computational attractiveness of II.

A Appendix: Technical assumptions and proofs

A.1 Technical Assumptions

The following notations are used. For a $d \times d$ matrix $A$ and a $c \times d$ matrix $B$, define $\|b\|_A := \sqrt{\text{Trace}(BAB^T)}$ and $\|b\| := \|b\|_{L^2}$. Define $\mathcal{N}_A(\theta^0) \subset \Theta$, $\mathcal{N}_B(\delta^0) \subset \mathcal{B}$ and $\mathcal{N}_A(0) \subset \Gamma$ as some generic open neighborhoods of radius $\delta$ for $\theta^0$, $\beta^0$ and $\gamma^0$ respectively. Finally, define

$$M(\beta, \gamma) := E \left[ \frac{D}{p(W; \gamma)} m(Y, Z, X, \beta) \right]$$

and $M(\beta, \gamma, \theta) := E \left[ \frac{D}{p(W; \gamma)} m(Y(\theta), Z, X, \beta) \right]$.

By the definition of $\beta^0$ in (1), the definition of the binding function in (15), and the above Lemmas,

$$M(\beta^0, \gamma^0) = M(\beta^0, \gamma^0, \theta^0) = 0. \quad (31)$$

**Assumption A1:**

(a) Structural Model in (8): $\varepsilon$ has a known distribution $F_\varepsilon = F_\varepsilon^0$ and is independent of $Z$ and $X$ whose unknown distribution is $F(Z, X) = F(Z, X)^0$.

(b) Strict overlap: For MAR in (2), $p_0(W) := P(D = 1|W) \in [p, 1)$ for a constant $p > 0$.

(c) Observed sample: $\{W_i, D_i, X_i^{\text{obs}} := D_i X_i\}_{i=1}^n$ are i.i.d. copies of $W, D$, and $X^{\text{obs}} := DX$.

**Assumption A2:** $\beta^0$ is the unique solution to equation (1).

**Assumption A3:** For all $\theta \in \Theta$, the binding function $\beta(\theta)$ defined in equation (15) satisfies $\beta^0 = \beta(\theta)$ if and only if $\theta = \theta^0$.

**Assumption A4:** There exists a unique $\gamma^0 \in \Gamma$ and a function $p(w; \gamma) : \text{Support}(W) \times \Gamma \mapsto (0, 1)$ such that $p_0(w) = p(w; \gamma^0)$ for all $w \in \text{Support}(W)$. $\Gamma \subset \mathbb{R}^{d_\gamma}$ is compact and $d_\gamma$ is finite.

**Assumption A5:**

(a) $\Theta \subset \mathbb{R}^{d_\theta}$ and $\mathcal{B} \subset \mathbb{R}^{d_B}$ are compact with $\theta^0 \in \text{interior}(\Theta)$ and $\beta^0 \in \text{interior}(\mathcal{B})$.

(b) For $l = (l_1, l_2, l_3)$ where $l_1 \in \text{Support}(Y)$ or $Y(\theta)$ (as appropriate) and $(l_2, l_3) \in \text{Support}(Z, X)$: $m(l, \beta)$ is continuous in $\beta$ for all $l$, and $\|m(l, \beta)\|_2 \leq g(l)$ for all $l$ and $E[g(l)] < \infty$.

(c) For $\delta > 0$:

$$\sup_{\theta \in \Theta, \beta \in \mathcal{N}_B(\delta^0), \gamma \in \mathcal{N}_A(\gamma^0)} \frac{\|M_{N, S}(\beta, \gamma, \theta) - M(\beta, \gamma, \theta)\|}{1 + \|M_{N, S}(\beta, \gamma, \theta)\| + \|M(\beta, \gamma, \theta)\|} = o_P(1).$$

**Assumption A6:**

(a) $p(w; \gamma)$ is continuous in $\gamma \in \Gamma$ for all $w \in \text{Support}(W)$.

(b) For some $\delta > 0$: $p(w; \gamma)$ is twice continuously differentiable in $\gamma \in \mathcal{N}_A(\gamma^0)$ for all $w \in \text{Support}(W)$, and the derivatives $p_\gamma(w; \gamma) := \frac{\partial}{\partial \gamma} p(w; \gamma)$ and $p_{\gamma\gamma}(w; \gamma) := \frac{\partial^2}{\partial \gamma^2} p(w; \gamma)$ satisfy: $\sup_{\gamma \in \mathcal{N}_A(\gamma^0)} \|p_\gamma(w; \gamma)\|^2 + \sup_{\gamma \in \mathcal{N}_A(\gamma^0)} \|p_{\gamma\gamma}(w; \gamma)\| < b(w)$ for all $w \in \text{Support}(W)$ where $b(w) \geq 0$ and $E[b(w)] < \infty$.

(c) The score $l_\gamma(D, W; \gamma) := (D - p(W; \gamma)) p'(W; \gamma)/[p(W; \gamma)(1 - p(W; \gamma))]$ is such that $B_0 := E[ l_\gamma(D, W; \gamma^0)p'_\gamma(D, W; \gamma^0) ]$ is nonsingular.
Assumption A7:

(a) For each \( l = (l_1, l_2, l_3) \) where \( l_1 \in \text{Support}(Y \text{ or } Y(\theta)) \) (as appropriate) and \( (l_2, l_3) \in \text{Support}(Z, X) \), \( m(l, \beta) \) is continuously differentiable in \( \beta \in \mathcal{N}_\delta(\beta^0) \) for some \( \delta > 0 \). Allow for changing the order of differentiation and integration, i.e., let \( E \left[ \sup_{\beta \in \mathcal{N}_\delta(\beta^0)} \left\| \frac{\partial}{\partial \beta'} m(l, \beta) \right\| \right] < \infty. \)

(b) \( G_0 := E \left[ \frac{\partial}{\partial \beta} m(Y, Z, X, \beta^0) \right] = E \left[ \frac{\partial}{\partial \beta} m(Y(\theta^0), Z, X, \beta^0) \right] \) is nonsingular.

(c) \( \sqrt{N} \xi_{N,S} \xrightarrow{d} N \left( 0, E \left[ \xi_{i,S} \xi'_{i,S} \right] \right) \) where \( \xi_{N,S} := \sum_{i=1}^N \xi_{i,S}/N \) for

\[
\xi_{i,S} := \frac{D}{p(W; \gamma^0)} m(Y, Z, X, \beta^0) - \frac{1}{S} \sum_{s=1}^S \frac{D}{p(W; \gamma^0)} m(Y(\theta^0), Z, X, \beta^0)
\]

(d) For \( \theta = \theta^0 \): \( (\partial/\partial \theta') M(\beta^0, \gamma^0, \theta) \) has rank \( d_\theta \) and is continuously differentiable in \( \theta \).

(e) For every positive sequences \( \{\delta_N\} \) and \( \delta_N = o(1) \)

\[
\sup_{\theta \in \mathcal{N}_N(\theta^0), \beta \in \mathcal{N}_N(\beta^0), \gamma \in \mathcal{N}_N(\gamma^0)} \sqrt{N} \left\| M_{N,S}(\beta, \gamma, \theta) - M(\beta, \gamma, \theta) - M_{N,S}(\beta^0, \gamma^0, \theta^0) \right\| \quad 1 + \sqrt{N} \left\| M_{N,S}(\beta, \gamma, \theta) \right\| + \sqrt{N} \left\| M(\beta, \gamma, \theta) \right\| = o_P(1).
\]

To establish the asymptotic properties of the GII estimator, additionally define for each \( h \):

\[
M^h(\beta, \gamma, \theta) := E \left[ \frac{D}{p(W; \gamma)} m(Y(\theta), Z, X, \beta) \right].
\]

As before like (31) and further using (27),

\[
M(\beta^0, \gamma^0) = M(\beta^0, \gamma^0, \theta^0) = M^{h=0}(\beta^0, \gamma^0, \theta^0) = 0. \tag{32}
\]

The following assumptions on \( M^h_N(\beta, \gamma, \theta) \) \( M^h(\beta, \gamma, \theta) \) and \( M(\beta, \gamma, \theta) \) are additionally maintained for the asymptotic equivalence of the GII and II estimators.

Assumption A8: For some \( \delta > 0 \) and a finite \( b > 0 \), let the following hold for \( M^h_N(\cdot) \) and its limit counterpart \( M^h(\cdot). \)

(a) \( \sup_{\theta \in \Theta, \beta \in \mathcal{N}_\delta(\beta^0), \gamma \in \mathcal{N}_\delta(\gamma^0)} \left\| M^h(\beta, \gamma, \theta) - M(\beta, \gamma, \theta) \right\| \leq b \times h \) for \( h \in [0, \delta) \).

(b) \( \sup_{h \in [0, \delta)} \sup_{\theta \in \Theta, \beta \in \mathcal{N}_\delta(\beta^0), \gamma \in \mathcal{N}_\delta(\gamma^0)} \frac{\left\| M^h_N(\beta, \gamma, \theta) - M^h(\beta, \gamma, \theta) \right\|}{1 + \left\| M^h_N(\beta, \gamma, \theta) \right\| + \left\| M^h(\beta, \gamma, \theta) \right\|} = o_P(1). \)

(c) (i) \( \sup_{h \in (0, \delta)} \sup_{\theta \in \Theta, \beta \in \mathcal{N}_\delta(\beta^0), \gamma \in \mathcal{N}_\delta(\gamma^0)} \left\| \frac{\partial}{\partial (\beta', \gamma')} M^h_N(\beta, \gamma, \theta) - M^h(\beta, \gamma, \theta) \right\| = o_P(1). \)

\[
^{10}\text{See Remark 4 for an explanation of these assumptions.}
\]
(c) \( \sup_{h \in (0, \delta)} \sup_{\theta \in \mathcal{N}_\delta(\theta^0), \beta \in \mathcal{N}_\delta(\beta^0), \gamma \in \mathcal{N}(\gamma^0)} \left\| \frac{\partial}{\partial \theta'} (M_N^h(\beta, \gamma, \theta) - M^h(\beta, \gamma, \theta)) \right\| = O_p(N^{-1/2}). \)

(d) \( \frac{\partial}{\partial (\beta', \gamma', \theta')} M^h(\beta, \gamma, \theta) \) is continuous in \( \beta, \gamma, \theta, h \) for \( (\beta, \gamma, \theta) \in \mathcal{N}_\delta(\beta^0, \gamma^0, \theta^0) \) and \( h \in [0, \delta) \).

(e) \( \sup_{h \in (0, \delta)} \frac{\sqrt{N} \| M_N^h(\beta^0, \gamma^0, \theta^0) - M^h(\beta^0, \gamma^0, \theta^0) \|}{1 + \sqrt{N} \| M_N^h(\beta^0, \gamma^0, \theta^0) \| + \sqrt{N} \| M^h(\beta^0, \gamma^0, \theta^0) \|} = o_P(1). \)

**Remark 1:** It is well known that by Assumptions \( A4 \) and \( A6 \), the maximum likelihood estimator \( \hat{\gamma}_N \) that gives \( \hat{p}_0(w) = p(w, \hat{\gamma}_N) \) for Step 0 of modified II satisfies:

\[
\sqrt{N}(\hat{\gamma}_N - \gamma^0) = B_0^{-1} \frac{1}{\sqrt{N}} \sum_{i=1}^{N} l_i(D_i, W_i; \gamma^0) + o_P(1). \tag{33}
\]

Also, (2), Assumptions \( A1(b)-(c), A5(a)-(b) \) and \( A7(a)-(b) \) and (33) give for \( \hat{\beta}_N \) from Step 1:

\[
\sqrt{N}(\hat{\beta}_N - \beta^0) = -G_0^{-1} \frac{1}{\sqrt{N}} \sum_{i=1}^{N} \tau_i + o_P(1) \tag{34}
\]

where \( \tau_i := \frac{D_i}{p_0(W_i)} m(Y_i, Z_i, X_i, \beta^0) - E \left[ \frac{D_i}{p_0(W_i)} m(Y, Z, X, \beta^0) \right] B_0^{-1} l_\gamma(D_i, W_i; \gamma^0) \). See, e.g., Chaudhuri and Min (2012) for (33) and (34). Similar steps and (13) give for \( \hat{\beta}_N(\theta^0) \) defined as:

\[
\hat{\beta}_N(\theta^0) := \arg_{\beta \in B} \{ M_{N,S}(\beta, \hat{\gamma}_N, \theta^0) = 0 \} \tag{35}
\]

the asymptotically linear representation as:

\[
\sqrt{N}(\hat{\beta}_N(\theta^0) - \beta^0) = -G_0^{-1} \frac{1}{\sqrt{N}} \sum_{i=1}^{N} \tau_{i,S} + o_P(1) \tag{36}
\]

where

\[
\tau_{i,S} := \frac{D_i}{p_0(W_i)} \frac{1}{S} \sum_{s=1}^{S} m(Y_{is}(\theta^0), Z_i, X_i, \beta^0) - E \left[ \frac{D_i}{p_0(W_i)} m(Y(\theta^0), Z, X, \beta^0) \right] B_0^{-1} l_\gamma(D_i, W_i; \gamma^0).
\]

Therefore, under Assumption \( A7(c) \) and for a fixed \( S \), using (33), (34) and (36) jointly give:

\[
\sqrt{N}(\hat{\beta}_N - \hat{\beta}_N(\theta^0)) = -G_0^{-1} \sqrt{N} \left[ \xi_{N,S} - C_0(\hat{\gamma}_N - \gamma^0) \right] \overset{d}{\to} N \left( 0, G_0^{-1} H_0 G_0^{-1} \right) \tag{37}
\]

where \( C_0 := \text{Cov}(\xi_{i,S}, l_\gamma(D_i, W_i; \gamma^0)) = E \left[ \frac{1}{p_0(W)} \{ m(Y, Z, X, \beta^0) - m(Y(\theta^0), Z, X, \beta^0) \} \right] \frac{\partial}{\partial \gamma} p(W; \gamma^0). \)

**Remark 2:** Assumption \( A5(c) \) is an uniform convergence condition for which the strict overlap assumption in \( A1(b) \) plays a crucial role. The same holds for the stochastic equicontinuity condition Assumption \( A7(e) \) that is similar to condition (iii) in Theorem 3.3 of Pakes and Pollard (1989), but additionally it allows for nuisance parameters close to their true values. Such
high-level assumptions need to be verified on a case-by-case basis [see, e.g., Cattaneo (2010) or Chaudhuri and Guilkey (2014)].

**Remark 3:** Since it is also well known how to account for random weighting matrix [see Lemmas 3.4 and 3.5 of Pakes and Pollard (1989)], we abstract from it in all the proofs below and instead directly assume that the weighting matrix $A_N$ is possibly based on some preliminary consistent estimators of the concerned parameters such that $A_N \xrightarrow{P} A$ where $A$ is a positive definite matrix. Hence in what follows let $\hat{\theta}_N := \hat{\theta}_N^M(A_N)$.

**Remark 4:** Assumption A8 is a high-level condition restricting the choice of kernels (e.g. logistic or normal) used within the smoothing step of the generalized II procedure. Essentially it imposes sufficient smoothness condition on $M^h(\cdot)$ to facilitate simple proofs of the desired asymptotic properties of the GII estimator. The denominators in A8(b) and (d) add slightly more generality (similar to those in A5(d) and A7(e)). The asymmetric treatment with respect to $(\beta, \gamma)$ and $\theta$ in A8(c) (i) and (ii) respectively is due to the fact that we do not formally establish $\sqrt{N}$-consistency of $\hat{\theta}_N^h$ prior to demonstrating its asymptotic normality. The stronger condition in (ii) bears resemblance with the assumptions on suitable central limit theorem for Jacobians in the weak identification literature (see Kleibergen (2005)).

### A.2 Proofs

**Proof of Proposition 1:** For notational simplicity, in what follows we drop the $S$ subscript from the definition of $M_{N,S}(\cdot)$. Hopefully, this is not too confusing since $S$ is assumed fixed.

The proof proceeds by showing that $\|M(\beta^0, \gamma^0, \hat{\theta}_N)\| = o_P(1)$. Under Assumptions A2 and A3, this condition is sufficient for $\hat{\theta}_N \xrightarrow{P} \theta^0$ by virtue of (31), (33), (34) [where the last two give: $\hat{\gamma}_N \in \mathcal{N}_\delta(\gamma^0)$ and $\hat{\beta}_N \in \mathcal{N}_\delta(\beta^0)$ respectively with probability approaching 1], and the continuity implied by Assumptions A1(b), A6(a) and A5(b). Note that by the triangle inequality:

$$
\|M(\beta^0, \gamma^0, \hat{\theta}_N)\| \leq \|M(\beta^0, \gamma^0, \hat{\theta}_N) - M(\hat{\beta}_N, \hat{\gamma}_N, \hat{\theta}_N)\| + \|M(\hat{\beta}_N, \hat{\gamma}_N, \hat{\theta}_N) - M_N(\hat{\beta}_N, \hat{\gamma}_N, \hat{\theta}_N)\|
$$

By (33), (34), and the continuity implied by Assumptions A1(b), A6(a) and A5(b), the first term on the right hand side, i.e., $\|M(\beta^0, \gamma^0, \hat{\theta}_N) - M(\hat{\beta}_N, \hat{\gamma}_N, \hat{\theta}_N)\|$ is $o_P(1)$. (33), (34) and Assumption A5(c) imply that the second term $\|M(\hat{\beta}_N, \hat{\gamma}_N, \hat{\theta}_N) - M_N(\hat{\beta}_N, \hat{\gamma}_N, \hat{\theta}_N)\|$ is $o_P(1)$. The definition in (26) implies that the third term $\|M_N(\hat{\beta}_N, \hat{\gamma}_N, \hat{\theta}_N)\| \leq \|M_N(\hat{\beta}_N, \hat{\gamma}_N, \theta^0)\| = \|M(\hat{\beta}_N, \hat{\gamma}_N, \theta^0)\| + o_P(1)$ where the equality follows from (33), (34) and Assumption A5(c). Since (33), (34) and, as before, the continuity of $M(\beta, \gamma, \theta^0)$ in $\beta$ and $\gamma$ imply that $\|M_N(\hat{\beta}_N, \hat{\gamma}_N, \theta^0)\| = \|M(\beta^0, \gamma^0, \theta^0)\| + o_P(1)$, it follows by (31) that the third term is also $o_P(1)$.

**Proof of Proposition 2:** For notational simplicity, again, in what follows we drop the $S$ subscript from the definition of $M_{N,S}(\cdot)$.

Since $\hat{\theta}_N \xrightarrow{P} \theta^0$, it follows by (31) and Assumption A7(d) that $\|\hat{\theta}_N - \theta^0\| = O_P \left(\|M(\beta^0, \gamma^0, \hat{\theta}_N)\|\right)$. Under our maintained assumptions and (33) and (34), it can then be shown that $\|M(\beta^0, \gamma^0, \hat{\theta}_N)\|$ and hence $\|\hat{\theta}_N - \theta^0\|$ is $O_P(N^{-1/2})$. Details are available from the authors. Given this, and that
our assumptions are essentially same as that in Theorem 3.5 of Pakes and Pollard (1989), the rest of the proof is also similar. Hence we only provide a sketch of the proof below, and highlight the differences that appear only to the end of the proof.

For now let $d_\theta = d_\beta$. Justifying by virtue of (33), (34) and the $\sqrt{N}$-consistency of $\hat{\theta}_N$, linearize $M_N(\hat{\xi}_N, \theta)$ in a $\sqrt{N}$-neighborhood of $\theta^0$ by the function [see, for example, Chen et al. (2003)]:

$$L_N(\theta) := M_N(\beta^0, \gamma^0, \theta^0) + \frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \beta'}(\hat{\beta}_N - \beta^0) + \frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \gamma'}(\hat{\gamma}_N - \gamma^0) + \frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \theta^0}(\theta - \theta^0).$$

Define $\theta^*_N = \arg \min_{\theta} \| L_N(\theta) \|$. For the application of Assumption $A7(e)$ in the remainder of the proof choose $\delta_N$ such that $\hat{\beta}_N \in \mathcal{N}_{\delta_N}(\beta^0)$, $\hat{\gamma}_N \in \mathcal{N}_{\delta_N}(\gamma^0)$, and both $\hat{\theta}_N, \theta^*_N \in \mathcal{N}_{\delta_N}(\theta^0)$. It can now be shown (details available from the authors) by (33), (34), Assumption $A7(e)$ and the $\sqrt{N}$-consistency of $\hat{\theta}_N$ that $\| M_N(\hat{\beta}_N, \hat{\gamma}_N, \theta) - L_N(\theta) \| = o_P(N^{-1/2})$ for both $\theta = \hat{\theta}_N$ and $\theta = \theta^*_N$, and thus, subsequently, by Assumption $A7(d)$ that

$$\sqrt{N}(\hat{\theta}_N - \theta^0) = \sqrt{N}(\theta^*_N - \theta^0) = o_P(1). \quad (38)$$

Now note by (35): $\hat{\beta}_N(\theta^0)$ satisfies $0 = M_N(\hat{\beta}_N(\theta^0), \hat{\gamma}_N, \theta^0)$. Expanding the right hand side gives:

$$0 = M_N(\beta^0, \gamma^0, \theta^0) + \frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \beta'}(\hat{\beta}(\theta^0) - \beta^0) + \frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \gamma'}(\hat{\gamma}_N - \gamma^0) + o_P(N^{-1/2}). \quad (39)$$

On the other hand, since $\theta^*_N = \arg \min_{\theta} \| L_N(\theta) \|$, it follows that $o_P(N^{-1/2}) = L_N(\theta^*_N)$. Hence by the definition of $L_N(\theta^*_N)$ and using $\sqrt{N}$-consistency of $\hat{\beta}_N$, $\hat{\gamma}_N$ and $\theta^*_N$ it follows that:

$$o_P(N^{-1/2}) = M_N(\beta^0, \gamma^0, \theta^0) + \frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \beta'}(\hat{\beta}_N - \beta^0)' + (\hat{\gamma}_N - \gamma^0)', (\theta^*_N - \theta^0)' \right)' . \quad (40)$$

Therefore, equating (39) and (40) gives:

$$\frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \theta^0} \sqrt{N}(\theta^*_N - \theta^0) = - \frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \beta'} \sqrt{N}(\hat{\beta}_N - \hat{\beta}_N(\theta^0)) + o_P(1).$$

Until now in this proof we have disregarded the over-identifying nature of the system with respect to $\theta$. However, when $d_\theta < d_\beta$, and $A_N \xrightarrow{L} A$ (positive definite), under Assumption $A7(d)$, standard methods modify the above relation as, up to an $o_P(1)$ term:

$$\frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \theta} A(\theta^0) \sqrt{N}(\theta^*_N - \theta^0) = - \frac{\partial M(\beta^0, \gamma^0, \theta^0)}{\partial \beta'} A(\theta^0) \sqrt{N}(\hat{\beta}_N - \hat{\beta}_N(\theta^0)).$$

Differentiating $M(\beta^0(\theta), \gamma^0, \theta^0)$ with respect to $\theta$ at $\theta = \theta^0$ and using Assumption $A7(d)$:

$$\frac{\partial}{\partial \theta^0} M(\beta^0(\theta^0), \gamma^0, \theta^0) = \frac{\partial}{\partial \beta^0} M(\beta^0(\theta^0), \gamma^0, \theta^0) \frac{\partial}{\partial \theta^0} \beta^0(\theta^0).$$

Since $\beta^0 = \beta^0(\theta^0)$ by Assumption $A3$, this gives

$$\frac{\partial}{\partial \theta^0} M(\beta^0, \gamma^0, \theta^0) = \frac{\partial}{\partial \beta^0} M(\beta^0, \gamma^0, \theta^0) \frac{\partial}{\partial \theta^0} \beta^0(\theta^0) = G_0 \frac{\partial}{\partial \theta^0} \beta^0(\theta^0)$$

Combining the above and using (37) and (38)
As before, by Assumptions
\[ \sum_{i=1}^{n} \mathbf{A}_i \mathbf{G}_i \mathbf{D}_i \mathbf{G}_i' \mathbf{A}_i' \]
we obtain:
\[
\sqrt{N}(\hat{\theta}_N - \theta^0) = \left[ \frac{\partial^2 \hat{\beta}_N(\theta^0)'}{\partial \theta^2} G_0' A G_0 \frac{\partial \hat{\beta}_N(\theta^0)}{\partial \theta} \right]^{-1} \frac{\partial \hat{\beta}_N(\theta^0)'}{\partial \theta} G_0' A \sqrt{N} \left[ \tilde{\xi}_N - C_0(\tilde{\gamma}_N - \gamma^0) \right] + o_P(1)
\]
\[ N(0, \Sigma(A)). \] 

**Proof of Proposition 3:** For notational simplicity, we will drop the \( N \) subscript from \( h \) (with the understanding that for any given \( N, h > 0 \) but \( h = o(N^{-1/2}) \)) and the \( S \) subscript from the definition of \( M_{h,S}^N(\cdot) \). Also, since the weighting matrix \( A_N \) can be handled in the same manner as in Propositions 2, we only consider the just-identified case \( (d_0 = d_\beta) \) and take \( A_N = A = I_{d_\beta} \).

The proof now proceeds in two steps, first we demonstrate consistency of \( \hat{\theta}_N \) for \( \theta^0 \), and we then demonstrate \( \| \hat{\theta}_N - \hat{\theta}_N^0 \| = o_P(N^{-1/2}) \). The entire proof closely follows that of Propositions 1 and 2 except that having established consistency we slightly deviate to emphasize the fact that \( M_{h}^N(\beta, \gamma, \theta) \) is indeed differentiable with respect to \( \theta \) for \( h > 0 \).

**Consistency:** Following Proposition 1, by continuity of \( M(\beta, \gamma, \theta) \) in \( \theta \), the result follows if \( \| M(\beta^0, \gamma^0, \hat{\theta}_N^h) \| = o_P(1) \) as \( h \to 0 \). This condition will be sufficient for \( \hat{\theta}_N \xrightarrow{P}{\theta^0} \) by the same arguments as Proposition 1. By the triangle inequality:

\[
\| M(\beta^0, \gamma^0, \hat{\theta}_N^h) \| \leq \| M(\beta^0, \gamma^0, \hat{\theta}_N^h) - M(\tilde{\beta}_N, \tilde{\gamma}_N, \hat{\theta}_N^h) \| + \| M(\tilde{\beta}_N, \tilde{\gamma}_N, \hat{\theta}_N^h) - M(h(\tilde{\beta}_N, \tilde{\gamma}_N, \hat{\theta}_N^h)) \| + \| M(h(\tilde{\beta}_N, \tilde{\gamma}_N, \hat{\theta}_N^h)) \| + o_P(1).
\]

As before, by Assumptions A1(b), A6(a) and A5(b), \( \| M(\beta^0, \gamma^0, \hat{\theta}_N^h) - M(\tilde{\beta}_N, \tilde{\gamma}_N, \hat{\theta}_N^h) \| = o_P(1) \). For the second term on the RHS of (41) note that, due to (33) and (34), \( \tilde{\gamma} \) and \( \tilde{\beta} \) belong respectively in \( \mathcal{N}_S(\gamma^0) \) and \( \mathcal{N}_S(\beta^0) \) with probability approaching one. Hence the second term is \( o_P(1) \) by Assumption A8(a) and the condition that \( h \to 0 \). Similar arguments give the third term on the RHS to be \( o_P(1) \) by virtue of Assumption A8(b). Finally consider the fourth term and note that:

\[
\| M(h(\tilde{\beta}_N, \tilde{\gamma}_N, \hat{\theta}_N^h)) \| \leq \| M(h(\tilde{\beta}_N, \tilde{\gamma}_N, \hat{\theta}_N^h), \theta^0) \| + o_P(1) = \| M(\tilde{\beta}_N, \tilde{\gamma}_N, \theta^0) \| + o_P(1) \]
\]
where the first inequality follows from (28) and the second by Assumption A8(b). Now, (i) the Lipschitz continuity of \( M^h \) in \( \mathcal{A} \), (ii) continuity of \( M(\cdot) \) with respect to \( \beta \) and \( \gamma \) that is implied by Assumptions A1(b), A5(b) and A6(a), along with (iii) (33) and (34) give for \( h \to 0 \),

\[
\| M(h(\tilde{\beta}_N, \tilde{\gamma}_N, \theta^0)) \| = \| M(\tilde{\beta}_N, \tilde{\gamma}_N, \theta^0) \| + o_P(1) = \| M(\beta^0, \gamma^0, \theta^0) \| + o_P(1), \]
\]
and this is \( o_P(1) \) by (32). Hence the fourth term is also \( o_P(1) \) and thus it follows that \( \hat{\theta}_N \xrightarrow{P}{\theta^0} \).

**Asymptotic equivalence:** In a just-identified model, \( \hat{\theta}_N \) satisfies the definition in (28) if

\[
o_P(1) = \sqrt{N} M_N^h(\beta, \tilde{\gamma}_N, \hat{\theta}_N^h).
\]

Denoting \( \zeta = (\beta', \gamma', \theta')' \) for simplicity, and expanding the RHS we obtain:

\[
o_P(1) = \sqrt{N} M_N^h(\zeta^0) + \frac{\partial}{\partial \beta'} M_N^h(\tilde{\zeta}_{\beta,N}) \sqrt{N}(\tilde{\beta}_N - \beta^0) + \frac{\partial}{\partial \gamma'} M_N^h(\tilde{\zeta}_{\gamma,N}) \sqrt{N}(\tilde{\gamma}_N - \gamma^0)
\]
\[+ \frac{\partial}{\partial \theta'} M_N^h(\tilde{\zeta}_{\theta,N}) \sqrt{N}(\tilde{\theta}_N - \theta^0).\]
for some (row-by-row) mean-values $\bar{\xi}_{\beta,N}$, $\bar{\xi}_{\gamma,N}$ and $\bar{\xi}_{\theta,N}$. Therefore, by $\sqrt{N}$-consistency of $\hat{\beta}_N$ and $\hat{\gamma}_N$ from (34) and (33), consistency of $\hat{\theta}^b_N$ (just established above), uniform convergence in Assumptions A8(c)(i) (applied to the second and third terms on RHS) and A8(c)(ii) (applied to the last term on RHS), the continuity assumption in A8(d), it follows that

$$o_P(1) = \sqrt{N}M^h_N(\zeta^0) + \frac{\partial M(\zeta^0)}{\partial \zeta'} \sqrt{N} \left[ (\hat{\beta}_N - \beta^0)' , (\hat{\gamma}_N - \gamma^0)' , (\hat{\theta}^b_N - \theta^0)' \right]' .$$

Finally take $\delta_N > 0$ and $\delta_N = o(N^{-1/2})$, and note that:

$$\sup_{h \in (0, \delta_N)} \sqrt{N} \| M^h_N(\zeta^0) - M_N(\zeta^0) \| \leq \sup_{h \in (0, \delta_N)} \sqrt{N} \| (M^h_N(\zeta^0) - M^h(\zeta^0)) - (M_N(\zeta^0) - M(\zeta^0)) \| \leq o_P(1) + \sqrt{N}b \times \delta_N$$

with probability approaching 1, respectively by Assumptions A8 (d) (along with the fact that $M(\zeta^0) = 0$) and (a). Since $\delta_N = o(N^{-1/2})$ as dictated by the statement of the Proposition, it now follows that $\sup_{h \in (0, \delta_N)} \sqrt{N} \| M^h_N(\zeta^0) - M_N(\zeta^0) \| = o_P(1)$ and hence

$$o_P(1) = \sqrt{N}M_N(\zeta^0) + \frac{\partial M(\zeta^0)}{\partial \zeta'} \sqrt{N} \left[ (\hat{\beta}_N - \beta^0)' , (\hat{\gamma}_N - \gamma^0)' , (\hat{\theta}^b_N - \theta^0)' \right]' = \sqrt{N}L_N(\hat{\theta}^b_N)$$

for $L_N(\theta)$ defined in the proof of Proposition 2. Therefore, $\| L_N(\hat{\theta}^b_N) \| = o_P(N^{-1/2})$. Now by following the same steps as in that proof we obtain $\sqrt{N}\| \hat{\theta}^b_N - \theta_N \| = o_P(1)$. \hfill \square

Table 1: Monte-Carlo results for the Multinomial probit $(J = 2)$ model. MBIAS, ABIAS, STD, IQR and COV95 are the mean bias, absolute bias, standard deviation, interquartile range and coverage of a 95% Wald-type confidence interval for the standard II estimator for the different elements of $\theta$ when $N = 5000$. STD is based on Monte-Carlo. Results are obtained by 10000 Monte-Carlo trials.

Table 2: Monte-Carlo results for the Multinomial probit \((J = 2)\) model. MBIAS, ABIAS, STD, IQR and COV95 are the mean bias, absolute bias, standard deviation, interquartile range and coverage of a 95\% Wald-type confidence interval for the concerned estimator for the different elements of the parameter vector \(\theta\). STD is not based on the asymptotic variance formula in Proposition 2 but on the Monte-Carlo. Results are obtained by 10000 Monte-Carlo trials.
Figure 1: Kernel density plots for the studentized IPW-II and IPW-GII estimators of the different elements of the parameter vector $\theta$ when sample size $N = 5000$. Results are reported based on 10000 Monte Carlo trials. It is clear that IPW-II can be far away from the standard normal approximation (red line) while IPW-GII does not suffer from this problem.
