The impact of regional health care coverage on infant mortality and disease incidence

Abstract

This paper investigates the effect of changes in the physician coverage ratio on infant mortality, perinatal mortality and the incidence of common childhood diseases. We utilize historical data and variation in the regional physician density provided by discriminatory policies in Germany in 1933, when Jewish physicians were expelled from health insurance schemes and subsequently emigrated in large numbers. The results indicate substantial health effects. One additional physician per 1,000 of population reduces infant mortality by 23% and perinatal mortality by 16%. We find similar negative effects for gastrointestinal diseases, stillbirths and the incidence of measles, influenza and bronchitis. Using a semiparametric control function approach, we demonstrate that the marginal returns to coverage are nonlinear and decreasing. A coverage ratio of two physicians per 1,000 of population is sufficient to prevent mortality effects in the population.

Keywords: infant mortality, physician coverage, health care supply, childhood diseases

1 Introduction

On average, 12,000 children under the age of one have died every day in 2015. Although progress has been made in reducing infant mortality, the distribution remains heavily skewed across countries. 99% of all infant deaths worldwide take place in developing countries, many of which have fallen short of reaching the Millennium Development Goal of reducing child mortality by two-thirds by 2015 relative to 1990 (You et al. 2015).\(^1\)

While these countries still have a long way to go, others have made considerable progress. The reduction in child mortality among today’s developed economies has been one of the most significant developments in public health over the last century. In Germany, 154 children out of 1,000 born died within their first year of life in 1915. In 1970, it was less than 25 and in 2015, the rate was down to 3.1, a decrease of 98% over a century. Today, infant mortality in developed countries occurs mostly due to premature birth, sudden infant death syndrome and congenital conditions. In contrast, 59% of infant deaths in the developing world result from infectious diseases such as diarrhoea, measles, acute respiratory infections and birth asphyxia (Andrews et al. 2008). The majority of health issues are related to malnutrition, bad sanitation and polluted water. However, fatalities could largely be prevented if access to trained health personnel were available (Andrews et al. 2008). Physicians provide prenatal care, attend birth, administer medication and can also influence their patients’ behaviour by encouraging health-related behavior and compliance with hygienic standards (cf. Stanton and Clemens 1987, Fewtrell et al. 2005, Terza et al. 2008).

For these reasons, the spatial distribution of physicians is a frequent policy concern. Rural shortages in health care are a well documented problem (e.g. Cutchin 1997); and medical brain drain migration affects developing countries worldwide (e.g. Mullan 2005, Docquiera and Rapoport 2011, Gibson and McKenzie 2011). Health professionals tend to leave lower income countries for the better earnings prospects in developed economies. The immediate consequences of these supply shortages are not well understood so far. However, there is a large macroeconomic literature on second-order effects of health, documenting that population health and mortality influence development in the long-run (e.g. Strauss and Thomas 1998, Lorentzen et al. 2008, Weil 2014). Understanding the short-run mechanics between health care coverage and health is vital to developing policies that can prevent lasting negative consequences.

Although cross-country studies have established a positive correlation between physician density and health, there is a lack of causal evidence how much an increase in the supply of physicians effectively improves health outcomes, if at all. The supply of physicians is endogenous to health care demand and a simple comparison of health outcomes between

---

\(^1\)Child mortality refers to the death of a child before reaching its fifth birthday and is highly correlated with infant mortality, with 75% of children dying before reaching the age of one.
regions will likely lead to biased estimates. However, knowing how much an additional physician affects public health is vitally important for health policy, especially since training physicians is expensive. In addition, the functional form of the response relationship is of special interest. Improving medical care may be especially effective in regions where coverage is sparse, whereas increasing supply in regions where levels are already high may increase luxury health care consumption, but do little to improve health outcomes.

We establish a causal link between physician coverage and public health by tracing exogenous shocks to the supply of physicians in a historical setting. For identification, we utilize a series of discriminatory policies that were introduced in Germany in 1933 which banned Jews from public positions and severely limited the professional activity of Jewish physicians. Jews were disproportionately overrepresented in the medical profession, with about 17% of physicians considered Jewish by the Nazi definition in 1933 (Kröner 1989). The distribution of the Jewish population varies across German municipalities, providing ample variation in the treatment intensity. Conceptually, this paper is related to a series of papers by Fabian Waldinger, who examines educational outcomes (Waldinger 2010), academic productivity and peer effects (Waldinger 2012a), the role of human and physical capital for the creation of scientific knowledge (Waldinger 2012b) and the link between German Jewish Emigrés and US inventions (Moser et al. 2014) in the context of the discriminatory laws and the subsequent dismissal of Jewish scientists from German universities.

There is a large literature investigating policies to reduce child and infant mortality rates in both economics and medical science (see Andrews et al. 2008, Kuruvilla et al. 2014). However, evidence regarding the importance of physicians is mixed. Papers focusing on the relationship between physician density and infant mortality mostly rely on cross-country comparisons, often focusing on single cross-sections (e.g. Kim and Moody 1992, Hertz et al. 1994, Anand and Bärnighausen 2004). Some papers use a panel data approach (e.g. Farahani et al. 2009, Bhargava et al. 2011, Chauvet et al. 2013) to control for the influence of time-invariant unobservable factors. The results from these studies vary. Some find a negative relationship between physician density and mortality, but many results are inconclusive. Micro data evidence is limited. Frankenberg (1995) examines the impact of access to health facilities and personnel on infant and child mortality in Indonesia using village-level data and a fixed effects approach and finds that a maternity clinic reduces the odds of infant mortality by 15% and an additional doctor by 1.7%. Lavy et al. (1996) provide evidence that increased supply of health staff and drugs can improve child health in rural areas in Ghana. They also evaluate the impact of health infrastructure on child outcomes, but are unable to find conclusive evidence. Aakvik and Holmås (2006) use a dynamic panel approach to estimate the effect of general practitioner density on mortality in Norwegian municipalities, but do not find a significant relationship.

A limiting factor of these studies is their inability to account for time-varying endogenous
changes in the supply of physicians. Moreover, sample sizes are often small and the data quality questionable (Hill et al. 2007, Farahani et al. 2009). Most low- and middle-income countries do not have well-functioning vital registration systems and estimates of the infant mortality rate often rely on a mixture of sources and reporting systems.

We contribute to the literature by tracking exogenous changes in the physician population coverage ratio using a comparatively large sample of administrative data. Detailed information on causes of death and disease incidence allows us to examine specifically which medical conditions physicians can influence, and to pinpoint where improving coverage is most effective. The historical setting also offers comparability. The health and disease environment in Germany in 1930 is similar to the situation in many developing countries today. Methodologically, we combine the traditional control function function approach with a partially linear semiparametric model in the spirit of Robinson (1988) and Baltagi and Li (2002) to get a non-parametric estimate of the dose-response function. Estimating the response function flexibly allows us to evaluate the hypothesis of diminishing returns to health care provision.

Our findings suggest that one additional doctor per 1,000 of population reduces infant mortality by about 18 cases per 1,000 live births. In our sample, one additional doctor is approximately equivalent to doubling the coverage ratio. Given an average infant mortality rate of 75, this corresponds to a decrease of 23%. Moreover, our results show that reductions occur for deaths from inflammatory bowel diseases, measles, influenza and bronchitis as well as stillbirths; which are among the main causes for mortality in developing countries today. Fatalities due to premature birth and congenital issues, for which medical treatment is difficult, are unaffected. Using the semiparametric instrumental variables approach, we demonstrate that mortality effects are highly nonlinear and disappear after a coverage ratio of about two physicians per 1,000 of population.

The remainder of the paper is structured as follows: section 2 compares the past health environment of developed economies to the situation in today’s developing countries, section 3 provides the institutional background for our analysis, section 4 reviews the data, section 5 discusses our empirical strategy, section 6 presents our results and section 7 concludes.

2 Historical context and external validity

Over the last 50 years, infant mortality in many low and middle income countries has decreased substantially. Infant mortality in South Asia, the Middle East and Sub-Saharan

\footnote{Other studies allow for a causal interpretation, but do not focus on the immediate relationship between physicians and infant health. Some paper focus on more specific treatments when estimating the effect of care utilization intensity on infant health, e.g. specialized hospital care for newborns (Almond et al. 2010, Almond and Doyle 2011). Other authors evaluate health care utilization in the general context of supply- or demand-side financing reforms (e.g. Gruber et al. 2014).}
Africa has decreased from around 160 infant deaths per 1,000 live births in the 1960s to between 40 and 60 in 2015 (see Figure A1). However, on average 12,000 children under the age of one still die every day in 2015 and almost all deaths occur in developing countries (You et al. 2015). Compositional differences matter as well: The past reduction in infant mortality rates occurred mainly due to a decrease in mortality in infants which have survived the first month. Neonatal mortality rates have not witnessed the same reduction (Bhutta et al. 2014, Lawn et al. 2011). The share of neonates in infant deaths has increased by around 10% in middle and low-income countries since 1990 (The World Bank 2016).

These changes in developing countries resemble the development of the industrialized economies a century ago (e.g. Cutler et al. 2006). Comparing the recent situation in developing regions to Germany in the 1930s reveals striking similarities (cf. Figure A1). In 1900, 207 infant deaths per 1,000 live births were registered in Germany. By 1933, the infant mortality rate had decreased markedly to 77. Much like today, this decrease was mainly driven by a reduction in mortality of infants which had survived the first month. The share of neonatal deaths in total infant deaths in Germany rose from 32% in 1890 to 52% in 1932 (Statistisches Bundesamt 1951). Historically, much of the decline in infant mortality in European countries at the beginning of the 20th century can be attributed to improvements in public health, sanitation and health practices (e.g. Loudon 1991, Cutler et al. 2006, Frohman and Brook 2006).

The main causes of death also differ substantially between countries at different stages of development. In developed countries, almost all remaining infant mortality is constituted by neonatal mortality due to preterm birth, sudden infant death syndrome and congenital conditions, which are medically difficult to treat. For developing countries, causes of infant death vary greatly with respect to postnatal age. Neonatal deaths are usually connected to inadequate access to basic medical care at and immediately following birth; the leading causes of neonatal death being infections (36%) such as sepsis, pneumonia, tetanus and diarrhoea, complications surrounding birth (27%) and asphyxia (23%). Low birth weight is often a contributing factor (Lawn et al. 2005, Andrews et al. 2008). Postneonatal mortality can be attributed to malnutrition, infectious diseases and home environment (Andrews et al. 2008). These causes are similar to those common in developed countries in the early 20th century. The majority of infant deaths then were attributable to deficient pre- and post-natal care, infections and water- and food borne diseases, most commonly respiratory infections and gastrointestinal illnesses (Reichsgesundheitsamt 1926–1945, Cutler et al. 2006). Much like today, these diseases disproportionately affected the poor due to their living and working conditions and insufficient nutrition (Frohman and Brook 2006).

---

3 Neonatal mortality refers to infants dying within the first 28 days of life (Andrews et al. 2008).

4 Around two-thirds of all births in developing countries occur at home and skilled-care is only available in about half of all cases. Postpartum visitation for the newborn is uncommon (Moss et al. 2002).
Another major difference between today’s developed and developing economies is the state of health care supply. Health care supply has increased substantially in the developed world over the last century. Germany currently has a physician coverage ratio of about four physicians per 1,000 of population. In 1930, supply was approximately one physician per 1,000 of population. This supply density is comparable to many developing countries today. Figure A2 displays physician coverage ratios for major world regions over the last 20 years. The lowest coverage ratio can be observed in Sub-Saharan Africa with less than 0.3 physicians per 1000 population. Average coverage ratios in the Middle East & Northern Africa as well as South Asia are closer to our sample average of one physician per 1,000 of population. Similar coverage ratios can be observed in countries many richer African or poorer Asian or Latin American countries, e.g. Bolivia, Pakistan or India.

Even though infant mortality rates, causes of death and coverage ratios are largely comparable between developing regions today and developed countries a century ago, the quality of health care has changed. Medical technology has advanced substantially since 1930. However, medical technology diffusion from developed to developing countries today is very limited. Figure A3 shows prevalence rates of selected medical technologies (magnetic resonance imaging and computed tomography units) across world regions.\(^5\) Especially in countries in South Asia and Sub-Saharan Africa, access to advanced medical technology is very limited. This lack of access is particularly pronounced for rural and poor population segments as medical technology in developing countries is usually concentrated in cities and private hospitals (Malkin 2007, Peters et al. 2008). Moreover, Perry and Malkin (2011) estimate that around 40% of health-care equipment in developing countries is out of service compared to less than 1% in developed countries.\(^6\) Access problems also extend to drugs, many of which are not available in low and middle income countries, especially in the public health sector. Even if certain medicines are available in the private sector, their price often substantially exceeds the international reference price which renders them prohibitively costly to large parts of the population (Cameron et al. 2009).

Moreover, much of modern medical technology is of limited relevance for addressing the main causes of infant mortality (e.g. Cutler et al. 2006, Andrews et al. 2008). Simple treatment measures are often sufficient to address many health issues. For example, gastrointestinal diseases are typically treated by ensuring sufficient rest, fluids, nutrition and possibly drugs to reduce fever and pain. In the case of birth asphyxia, resuscitation

---

\(^5\)In the context of infant mortality, data on ultrasound and incubator prevalence would be preferable. However, such data is unavailable. The available evidence suggests that supply is equally poor (Lawn et al. 2010, Ruiz-Peláez et al. 2004).

\(^6\)The lack of a reliable energy supply also constitutes a major hindrance to the employment of medical technology in developing countries. This is especially relevant for therapeutic devices such as neonatal incubators which need to be powered constantly. It is also of consequence for drugs and vaccines who need to be stored at low temperature to remain viable (Howitt et al. 2012).
by tactile stimulation or the clearing of upper airway secretions using a covered finger or oral mucus trap is normally sufficient. A need for external ventilation is only given in exceptional circumstances (Moss et al. 2002). Furthermore, early diagnosis, disease prevention and health practices are often more important than treatment after a health problem has fully developed. Physicians play an important role in disease prevention by ensuring health and sanitary practices. Especially for perinatal deaths, pre- and post-natal care practices are a crucial factor (Cutler et al. 2006). For example, proper umbilical care by physicians using antibacterial agents after birth has been shown to reduce infection of the cord and neonatal sepsis (Moss et al. 2002). Late-onset sepsis can be prevented by ensuring a clean caregiving environment. Similarly, a frequent problem in developing countries is hypothermia which affects more than half of all newborns and is associated with increased risk of neonatal infections, acidosis, coagulation defects, respiratory distress syndrome and brain haemorrhage. Neonatal incubators are only needed in extreme cases and hypothermia can generally be prevented by simple measures such as ensuring a warm environment during delivery, early breastfeeding, proper bathing, drying/swaddling and skin-to-skin contact with the mother (Moss et al. 2002).

The importance of health practices is mirrored in modern development economics (e.g. Dupas 2011). A large body of research focuses on how physicians can influence their patients’ well-being by encouraging health-related behavior and compliance with hygienic standards (cf. Stanton and Clemens 1987, Fewtrell et al. 2005, Terza et al. 2008). Similarly, propagation of sanitary practices was also the leading sentiment in health policy in the early 20th century (Frohman and Brook 2006). The germ theory of disease was already well established at the time and the importance of a sanitary environment for the prevention of diseases was understood. In fact, many practices recommended by development organizations today are similar to those of physician organizations in Germany during the early 20th century. An example is the recommendation of exclusive and immediate breastfeeding, in particular for low birth weight newborns (Moss et al. 2002). Exclusive breastfeeding in the first six month of life minimizes the risk of malnutrition and reduces the incidence of pneumonia in infants by 15-23% (Andrews et al. 2008, Howitt et al. 2012). Similarly, efforts at reducing infant mortality in the Weimar Republic also focused on the promotion of breastfeeding and the adoption of sanitary procedures such as sterilization of water and milk, among others. The propagation of such practices was primarily carried out through infant welfare centres staffed with both physicians, nurses and social workers who provided free medical examination to both mothers and their infants. Similar to development research today, policy debates focused on how to establish physicians as a recognized authority and improve compliance with their recommendations (Frohman and Brook 2006).

A field where technological progress has been very influential are vaccinations. Although many vaccines were invented during the first half of the 20th century (e.g. Rabies, Plague,
Diphteria, Pertussis, Tuberculosis, Tetanus and Yellow Fever) vaccination rates were still relatively low. Immunization rates increased sharply after 1960, and vaccinations for many important childhood diseases were invented afterwards (e.g. Polio, Measles, Mumps, Rubella and Hepatitis B). However, even though morbidity consequences from these diseases are high, historical data suggests that direct mortality due to them was rare even prior to the availability of vaccines (e.g. Cutler et al. 2006). The exception to this is Tuberculosis, which we exclude from the empirical analysis. To illustrate, the measles mortality rate in Germany in 1930 amounted to about 2 cases per 100,000 of population. This figure is comparatively low compared to mortality from Pneumonia (approx. 80 cases per 100,000 of population) or total infant mortality (7,500 per 100,000 live births). Furthermore, even though immunization rates have increased steadily in developing countries over the last 20 years, vaccination is still far from universal especially among poorer population segments (WHO 2016). Another important development was the discovery of antibiotics. Although penicillin was discovered in 1928, antibiotics were not commercially available for civilians before 1945. However, antibiotics as an antimicrobial drug are not effective against viral diseases such as Influenza or Bronchitis. Other commonly prescribed drugs were already available in 1930. Simple nonsteroidal anti-inflammatory drugs (e.g. acetylsalicylic acid, introduced as Aspirin by Bayer in 1899) and common pain and fever medications (e.g. Phenacetin, which metabolizes to Paracetamol, introduced in 1887) were readily sold in pharmacies (Jeffreys 2008).

In the remainder of the paper, we analyze historical data from Germany, one of today’s developed economies. The historical context may not provide a perfect control case in every dimension, but we believe the health and disease environment is sufficiently similar to allow inferences regarding the effect of care coverage on many traditional causes of infant mortality in present-day developing economies. For those conditions where medical technology has advanced, treatment efficiency is unlikely to deteriorate, in which case estimates can be considered a lower bound of the true effect. An additional advantage of the historical setting is that population statistics and vital registration systems were already established in Germany in the early 20th century, providing more reliable data and more accurate estimates than are often available for developing countries.

3 Institutional Background

The 1933 German census registered 499,682 residents of Jewish faith. Overall, this constituted only a small share of the then total German population of about 65 Million, 0.77%. Since the census registered only citizens who confessed to the Jewish faith, this measure constitutes a lower bound for the share of the population considered Jewish by the extended definition introduced by the National Socialist Party. The Jewish population was distributed across all German regions, but concentrated in urban regions with over...
70% of Jews residing in larger cities compared to 30% of the entire population. Figure 1 shows the spatial distribution of the Jewish population across German districts. The relatively smallest Jewish communities are located in rural areas in the north and the south. The largest Jewish communities lived in Frankfurt am Main (4.71%), Berlin (3.78%) and Breslau (3.23%). However, even though Jews constituted only a small part of the total population, they were disproportionately overrepresented in skilled occupations, especially in the medical profession. 10.9% of all doctors were of Jewish faith and approximately 17% were considered Jewish by the Nazis. In some municipalities, these figures were considerably higher. In Berlin, around 52% of all doctors were considered non-Aryan in 1933 (Kröner 1989).

Shortly after seizing power in 1933, the Nazi government introduced discriminatory policies that limited the professional activity of Jewish citizens. On April 7, 1933, the NSDAP passed the Gesetz zur Wiederherstellung des Berufsbemtentions [Law for the restoration of the professional civil services]. The law decreed that civil servants of non-
Aryan descent or with dubious past political activity could not be trusted to be loyal to the state and were to be placed in retirement effective immediately. An implementation decree further specified that it was sufficient to have one Jewish grandparent to be considered of non-Aryan descent. Exceptions were granted to those who had been employed since before August 1, 1914 or who had served in the First World War. However, this privilege could be declared exempt if a person was judged to be politically unreliable, an exception that was invoked frequently. This meant that non-Aryan doctors were forced into retirement at universities, publicly funded hospitals and all public medical institutions. By May 6, 1933 two executive orders extended the law to ordinary state employees, forcing resident physicians out of work as well.

On April 22, the law was followed by the Verordnung über die Zulassung von Ärzten zur Tätigkeit bei den Krankenkassen [Decree on the accreditation of doctors for health insurance funds], which withdrew the licence to practice for the compulsory health insurance fund from Jewish and other non-Aryan physicians. The same exceptions as above applied, but could again be declared void if the physician could be shown to have been active as a communist. The term communist was interpreted broadly and could also include social democratic physicians (Kröner 1989, Leibfried and Tennstedt 1980). Shortly after, an agreement between the association of German doctors and the association of private health insurance providers from July 1933 declared that bills from non-Aryan doctors were only reimbursed if they were subject to the exception clause or if the patient himself was of non-Aryan descent (Böhle 2003). This effectively expelled Jewish doctors from private health insurances as well.

Finally, a directive by the Reichsärztekommissar [Federal commissioner of physicians] from August 1933 specified that doctors of Aryan and non-Aryan descent were no longer allowed to stand-in for one another nor to refer patients to each other or to consult (Beddies et al. 2014). This also applied to non-Aryan physicians who profited from the exception clause and was especially harmful for specialists, who depended on referrals. According to the Reichsvertretung der Juden in Deutschland [Representation of German Jews], the directive rendered it virtually impossible for non-Aryan physicians to work in private hospitals and made the license for compulsory health insurance practice often worthless for those who still had one (Kröner 1989). The only remaining options for Jewish doctors were to emigrate, to find work in a Jewish hospital or to go into private practice. However, Klingenberger (2001) estimates that in 1930 there were only around 600,000 private patients in Germany, compared to a total population of around 65 million. This suggests that private practice could only provide a means of existence for a limited number of physicians and would be associated with a severe reduction in income. Considering their future in Germany, many Jewish physicians opted to emigrate. The data confirms

---

7 Health insurance was compulsory for all employees with an income of less than 3,600 Reichsmark. The average income in 1927 was 1,742 Reichsmark (Klingenberger 2001).
this. In 1933, there were 51,527 physicians in Germany, of which 5,557 were of Jewish faith. Our sample covers approximately 45% of the German population and we observe over 2,700 physicians who emigrate until 1936. The Jewish physicians who remained in Germany finally lost their medical licence in September 1938. At this point, preparations for war were already under way. A year later, on September 1, 1939, Germany invaded Poland, initiating the Second World War.

4 Data

The dataset is assembled from a variety of historical sources. The population and mortality figures are taken from the Reichsgesundheitsblatt [Health bulletin] (eds. 1927–1936), a yearly statistical publication by the health ministry of the German Reich. The data covers all municipalities with a population above 15,000. It tracks yearly changes in the municipal population. Available information includes total population figures, the number of births, marriages, and deaths. Mortality information is available in detailed categories in accordance with the International List of Causes of Death (ILCD-4, approximately corresponding to the International Classification of Diseases ICD-10 in use since 1990). The disease categories were expanded and partially redefined in 1930, restricting the coverage period for some variables. Panel attrition is negligible since the population threshold of 15,000 was not adhered to strictly. There are a few municipalities who merge or split during the observation period. The affected municipalities have been harmonized to the municipal structure in place in 1933.

Information about the number of physicians is taken from the Reichs-Medizinal-Kalender/Verzeichnis der deutschen Ärzte und Heilanstalten [Register of German physicians and hospitals], a yearly publication listing physicians in Germany for each municipality. The register includes the full name, address and specialization. The publication also tracks physicians who cease practicing and émigrés between years. Emigration before 1933 is negligible and figures increase substantially afterwards. We observe emigration of physicians each year for every municipality. Considering the names and the migration destinations of the émigrés, it is evident that the majority are of Jewish heritage. The yearly emigration figures are the main instrument used in the empirical analysis.

In addition, we construct alternative measures of the treatment intensity in 1933. Editions of the Reichs-Medizinal-Kalender after 1936 explicitly tag Jewish physicians (considered Jewish by the extended definition). From this, we construct a measure of Jewish physicians per municipality. Furthermore, we know the exact amount of people of Jewish faith in each municipality from the official population census conducted in 1933, just when the discriminatory measures where implemented. We use both the number of Jewish physicians remaining after 1936 and the local Jewish population in 1933 to proxy
for the number of Jewish physicians expelled in 1933. Although both variables are only imperfect proxies, when using them as instruments, the measurement error is not going to affect the estimates if the propensity to remain in 1936 or to become a physician is constant within the Jewish population. More general, the measurement error in the proxy will not confound the estimates unless it is correlated with municipal unobservable factors that are related to health.

The main analysis focuses on infant mortality, i.e. the number of children dying within the first year after birth and perinatal mortality, defined as the number of fetal (stillbirths) and neonatal (up to one week postpartum) deaths. We also look at the few specific causes of death for infants that are listed in the data, inflammatory bowel diseases (IBD) and premature birth or congenital defects. Additional outcomes are the population disease incidence figures for a number of common childhood diseases. The analysis uses incidence rates to track mortality effects. Infant mortality is measured as deaths in year $t$ per 1,000 live births in $t-1$, stillbirths are recorded per 1,000 births in $t-1$ and disease mortality incidence per 1,000 of population in $t-1$. Similarly, the physician coverage ratio is expressed as physicians per 1,000 of population in $t-1$. These expressions are commonly used in epidemiology and allow comparisons with other work. Relative incidence is the more interesting target parameter in this context and also helps to abstract from trends in birth rates. We use lagged values for the reference population instead of current ones to contain endogenous feedback effects. In addition, the unadjusted mortality figure distributions feature overdispersion and a long right tail typical for count data. Rescaling reduces skewness and alleviates these issues to some degree. Figure A4 compares the original and the scaled distributions for selected variables and illustrates that in many cases, anchoring mortality incidence to a reference population leads to a distribution that is approximately normal. For some variables, especially those with a comparatively large share of zero observations, the scaled distribution remains right-skewed. We address this issue in section 5.

The final sample is a balanced panel comprising 2,853 observations in 317 municipalities between 1928–1936. Our dataset covers 29,168,080 people in 1933, about 45% of the total German population at the time. By construction, the sample is selected on larger, more populous and urban municipalities. Descriptive statistics are given in Table A1 in the appendix. Although persons of Jewish faith number only 0.6% of the population, Jewish physicians account for about 7% of all physicians in our sample. This differs slightly from the 10% reported to be of Jewish faith in official aggregate statistics due to the timing of the measurement and the difference in the definition of who is considered Jewish. For every 1,000 live births, about 75 children die before reaching one year of age. The physician coverage ratio is approximately one per 1,000 of population.

To illustrate the dynamics in the data, Figure 2 depicts trends in the physician coverage and infant deaths per municipality over time, partitioned by Terciles of the municipal
Jewish population share in 1933. The graph shows a distinct drop in the number of physicians in 1933 in municipalities with a higher share of Jewish residents. Similarly, the number of infant deaths increases in these municipalities after 1933. However, it is also evident that the number of physicians begins to recover after 1934. Although the discriminatory policies cause a decline in the number of licensed physicians, they do not prevent endogenous locational sorting of physicians into municipalities with vacancies and higher demand for medical services in the following years. Especially for younger physicians who just finished their residency, the situation constitutes a good opportunity to open up practice in municipalities where more positions are left vacant. Historical evidence suggests that in later years, vacant positions and licenses for the public health insurance fund were awarded preferentially to young SA- and NSDAP-physicians (Leibfried and Tennstedt 1980). For this reason, we prefer using the yearly emigration figures as the instrument in the empirical analysis. Opposed to an intensity measure at a single point in time, the time-variant instrument can account for the dynamic selection process.
5 Empirical Strategy

5.1 Identification and linear model

Identifying the effect of physician coverage on health outcomes is hampered by a series of selection problems. Most importantly, health care supply is endogenous to health care demand. Physicians tend to locate in places where their services are in demand, leading to a positive association between sickness prevalence and health care services. The endogenous locational choice of practice has long been recognized. The geographic distribution of physicians has and continues to receive a lot of attention, from economics, medical science and policy makers alike (e.g. Cooper et al. 1977, Newhouse et al. 1982, Fruen and Cantwell 1982).

Moreover, certain market failures have been documented in health care markets which strengthen the positive relation between health care supply and demand. Supplier-induced demand arises from the information asymmetry between physicians and patients and leads to the oversupply of medical services in excess of individuals’ medical needs (Newhouse 1970). Persistent small area variation can also lead to a positive association between health care and health (Wennberg and Gittelsohn 1973). Since the 1970s, an extensive literature has documented real world occurrences of both phenomenons in many segments of the health care sector.

In addition, physicians are aware of local competition and vacancies when opening practice. Our main data source, a register of physicians in Germany first published in 1880, served as a work of reference that could also help ascertain the market when deciding where to open practice. Today, specialized consultancy services and a wealth of information regarding local market demand and coverage ratios are available to help physicians decide where to locate.

These persistent features of health care markets make it notoriously difficult to identify the degree to which changes in health care coverage influence the health of the population. Consider a regression equation of mortality incidence $y$ on physician supply $s$ in municipality $i = 1, \ldots, N$ in year $t = 1, \ldots, N$,

$$y_{it} = \beta s_{it} + \eta_i + \delta_t + \epsilon_{it} ,$$

(1)

where $\eta_i$ and $\delta_t$ are panel and time fixed effects and $T \ll N$. Estimates for $\beta_1$ from this equation are typically biased upwards due to positive selection.

We are using exogenous shocks to the supply of physicians to identify the causal effect of physician coverage on population mortality incidence. The 1933 law causes a drop in the number of registered physicians (cf. Figure 2). However, a naive before-after comparison is insufficient to eliminate endogeneity, since it does not account for the intensity with
which a municipality is affected and the dynamic selection into vacancies in the following
years. The one-time change does not prevent physicians from subsequently sorting into
municipalities where their services are needed and offer large potential rewards. In the
empirical analysis, we are using an instrumental variables approach to trace exogenous
variation in health care. Our main specification uses the variation in the number of
registered physicians induced by the emigration of Jewish physicians. Specifically, we are
augmenting the structural equation (1) with the first stage regression

\[ s_{it} = \alpha z_{it} + \psi_i + \theta t + \nu_{it}, \]

where \( z_{it} \) measures the yearly emigration of physicians per municipality, i.e. number of
physicians who give up their residency and move to a foreign country. We estimate the
system by two-stage least squares. Control function estimates are numerically equivalent.
This is our preferred specification, as the time-variant instrument emigration also accounts
for dynamic selection, and health effects may only materialize with some delay. Nevertheless,
we extend our analysis by using a measure of all Jewish physicians after 1933 and the
local Jewish population in 1933 as instruments. These measures only proxy for treatment
intensity at a single point in time. Even though they are time-invariant after 1933 and
have significantly less power, results are comparable considering some degree of positive
selection remains.

The assumptions implicit to this estimation procedure are discussed in turn. Monotonic-
ity (or in the linear case, homogeneity in the form of a common \( \alpha \)), i.e. that emigration of
physicians can only influence the total number of physicians in one direction or not at
all is likely fulfilled: Outmigration reduces the number of registered physicians, unless
excess migration of physicians from other municipalities would immediately overcompen-
sate for the reduction. Another possibility is that the market were fully saturated and
non-registered German physicians working in other professions now overcompensate for
the reduction due to emigration. These scenarios do not seem plausible. Relevance is an
empirical issue. Emigration of physicians naturally reduces the count of registered doctors.
First stage results show a significant negative effect that is statistically indistinguishable
from a one-to-one relation. The exclusion restriction is that changes in the propensity
to migrate (or in the level of Jewish physicians) only influence population health by
affecting the overall level of physicians. This means migration must be unrelated to other
time-variant factors that influence mortality. A valid concern is that a violation may be
caused by non-random assignment of the instrument, i.e. if the spatial distribution of
Jewish physicians is correlated with other features that impact population health in a way
that is not absorbed by municipality or time fixed effects. Jewish communities were more
prevalent in certain regions within Germany and also within metropolitan areas. Should
health and population dynamics differ substantially between more and less populous or
urbanized regions, the exclusion restriction may be violated such that $E[z_{it}\epsilon_{it}] \neq 0$. This concern is partly alleviated by the fact that our sample is already preselected on more populous, urban municipalities. Nevertheless, we address the issue of population dynamics in detail in the robustness checks and show that our results are unlikely to be driven by these factors.

5.2 Semiparametric model

A simple linear specification as given in (1) may not fully capture the mortality reduction of physician coverage. Mortality is a drastic outcome. The effect is most likely nonlinear, as an additional doctor in a region with sparse coverage can prevent more infant deaths compared to an additional doctor in a saturated region. After a certain coverage ratio has been reached, mortality effects are likely to taper off. Effects on morbidity and general quality of life possibly persist, but systematic fatality reductions beyond a lower bound of medically difficult cases are unlikely. We investigate this by employing a semiparametric approach using a partially linear model. We use the Baltagi and Li (2002) semiparametric fixed-effects estimator in combination with a control function (e.g. Heckman and Robb 1985) to get a flexible estimate of the effect of physicians on infant mortality.

Consider a general panel model of the form

$$y_{it} = f(s_{it}) + \eta_i + \epsilon_{it}.$$  \hspace{1cm} (3)

Time fixed effects are dropped for notational convenience. To control for the endogeneity in the physician supply $s_{it}$, we add the control function $\hat{\nu}_{it}$ for $s_{it}$ obtained from (2) to the model as a linear term,

$$y_{it} = f(s_{it}) + \hat{\nu}_{it}\rho + \eta_i + \zeta_{it}.$$  \hspace{1cm} (4)

The control function approach assumes that the correlation between the structural error $\epsilon_{it}$ and the first stage error $\nu_{it}$ can be described as linear relationship $\epsilon_{it} = \nu_{it}\rho + \zeta_{it}$ with $E[\nu_{it}\zeta_{it}] = 0$. The endogenous variation in $s_{it}$ is corrected using the estimated control function $\hat{\nu}_{it}$.

We estimate this model using the first difference approach described in Baltagi and Li (2002), as the conventional Robinson (1988) double residual estimator cannot accommodate the municipality-specific intercepts. To eliminate the fixed effects, differentiate (4) with respect to time,

$$\Delta y_{it} = \left\{ f(s_{it}) - f(s_{it-1}) \right\} + \Delta \hat{\nu}_{it}\rho + \Delta \zeta_{it}.$$  \hspace{1cm} (5)

Baltagi and Li (2002) show that $f(s)$ can be approximated by a series $p^k(s)$, and
\( \{ f(s_{it}) - f(s_{it-1}) \} \) by \( \{ p^k(s_{it}) - p^k(s_{it-1}) \} \). Equation (5) can be rewritten as

\[
\Delta y_{it} = \{ p^k(s_{it}) - p^k(s_{it-1}) \} \gamma + \Delta \hat{\nu}_{it} \rho + \Delta \zeta_{it} .
\] (6)

We use cubic B-splines to approximate \( f(s_{it}) \) and \( f(s_{it-1}) \). Having estimated the series terms, \( \gamma \) and \( \rho \) can be estimated with least squares from (6). The estimates can be used to fit the fixed effects \( \hat{\eta}_i \). Together, the estimates can be used to get the partialled-out residuals

\[
\hat{u}_{it} = y_{it} - \hat{\nu}_{it} \hat{\rho} - \hat{\eta}_i = f(s_{it}) + \zeta_{it} .
\] (7)

We then fit \( f(\cdot) \) by regressing the residual \( \hat{u}_{it} \) on \( s_{it} \) using local polynomial regression. The first derivative of the obtained function with respect to \( s \) is the desired marginal effect, \( dy/ds = df(s)/ds \).

### 5.3 Exponential model

The model specified in equations (1) and (2) may also be inadequate because of the non-negative nature of the dependent variable. Although rescaling reduces the long right tail in the original count distribution for many variables, this does not work equally well in all cases (cf. Figure A4). Especially when the original variable has generally low incidence that is spread over a comparatively large reference population, the transformed data still resembles typical count data distributions, but is not discrete anymore.

We propose an alternative model specification to address this issue as a robustness check. In addition to the triangular model above, we estimate an exponential conditional mean model with multiplicative error structure (e.g. Mullahy 1997, Windmeijer and Santos Silva 1997)

\[
y_{it} = \exp(\beta s_{it} + \eta_i + \delta_t + \epsilon_{it})
= \exp(\beta s_{it} + \eta_i + \delta_t) \nu_{it}
= \mu_{it} \nu_{it} .
\] (8)

For \( E[y_{it} | s_{it}] = \mu_{it} \), the error term in (8) must have a conditional unit mean, i.e. it must be that \( E[\nu_{it} | s_{it}] = 1 \). This implies that

\[
E \left[ \frac{y_{it} - \mu_{it}}{\mu_{it}} \right] | s_{it} \right] = 0 ,
\] (9)

which will typically be violated due to endogeneity in the number of physicians \( s_{it} \). Instead, we assume a conditional moment condition based on the orthogonal instrument \( z_i \) which
satisfies
\[ E \left[ \frac{y_{it} - \mu_{it}}{\mu_{it}} \Big| z_{it} \right] = 0. \] (10)

Using moment conditions based on (10), estimation by GMM is straightforward. The exponential class of models does not suffer from the incidental parameters problem, so including fixed effects does not pose a problem. Even though non-linear, the model features constant relative effects that are intuitive to interpret as incidence rate ratios. The exponentiated coefficients express the multiplicative change in the dependent variable given a unit increase in the independent variable. Since we only specify one conditional moment, the recursive interpretation of equations (1) and (2) is lost. In fact, this limited-information approach requires less assumptions than two-stage least-squares, as we make no assumptions about the distribution of \( s_{it} \) given \( z_{it} \) (cf. Cameron and Trivedi 2013).

6 Results

6.1 Infant and perinatal mortality

The main results are presented in Table 1. The reported coefficients can be interpreted as the effect on mortality if the coverage ratio increases by one additional physician per 1,000 people. Since the mean coverage ratio in the sample is 1.05, the estimates also approximately indicate the effect of doubling the coverage ratio.

The first panel in Table 1 shows the results when directly regressing health outcomes on physician coverage. For any outcome, the effect is indistinguishable from zero. The next panel shows our preferred specification, instrumenting the physician coverage ratio with the emigration figures. Looking at column (1), we find that one additional physician reduces overall infant mortality by about 18 cases per 1,000 live births. The average yearly infant mortality prior to 1933 is about 80. In relative terms, doubling the coverage ratio reduces infant mortality by about 23%.

For infant deaths caused by inflammatory bowel diseases (ulcerative colitis, enteritis, diarrhea or other ulcerations of intestines), a prominent cause of death for young children, especially in conditions of sub-standard hygiene and contaminated drinking water, we also find a significant negative effect. This effect is even larger in relative terms, presumably since gastrointestinal diseases were already known as a prominent cause of infant mortality in the 1930s.

Regarding perinatal mortality (column 3), the results indicate that increasing the physician coverage ratio by one reduces perinatal mortality by 10 cases per 1,000 births. Comparing the estimate with those in columns (4) and (5), we find that the effect is mainly driven by a reduction in the number of fetal deaths, not deaths of neonates. This is an

Notes: Infant mortality variables are measured per thousand live births in \( t - 1 \), perinatal mortality per thousand total births in \( t - 1 \). Registered physicians are measured per thousand of population in \( t - 1 \). Included instruments are a full set of year and municipality dummies. Excluded instruments are given in the respective paragraph header if applicable. Standard errors clustered at the municipality level given in parentheses. *, **, *** denote significance at the 0.1, 0.05, 0.01 level respectively.

Intuitive result. Medical complications arising from premature birth and congenital debility are notoriously difficult to treat and account almost completely for the remaining cases of infant mortality in developed economies today. Note that the number of observations for this set of regressions is lower due to a shorter coverage period in the data.

Comparing the results using emigration as the instrument (second panel) to the alternative instruments (panels three and four), results are mostly similar. All estimates are significant, except for perinatal mortality where power is lower due to the smaller sample size. Furthermore, all results are comparable in magnitude, albeit consistently slightly smaller. This may be due to the fact that the instruments are time invariant (after 1933), and although they factor in the magnitude of the policy change in 1933, they cannot account for the selection of physicians into municipalities with vacancies in later years.
6.2 Disease incidence

We extend our analysis to mortality rates from a set of diseases that, although not limited to, are a common cause of death for children. All variables are stated as population incidence per 1,000 persons. Not all diseases are equally common. Influenza, bronchitis and pneumonia are among the more frequent causes of death with between one to eight deaths per 10,000 individuals. Typhoid/paratyphoid fever and other bacterial infections were already less prevalent in the 1930s due to improving hygiene conditions and water preparation.

The results for disease incidence are given in Table 2. We find that one additional physician can decrease mortality due to measles by 1.3 cases per 100,000. Similarly for influenza and bronchitis we find that incidence is reduced by about 4.5 cases per 100,000. Given the comparatively low baseline incidence, these effects are substantial. We cannot reject a zero effect for scarlet fever, diphteria and pneumonia. Except for diphteria, the estimates are negative but too imprecisely estimated to allow any conclusion.

6.3 Nonlinear mortality effects

Results for the semiparametric analysis are presented in Figure 3. Panel (a) plots an estimate of the conditional mean function using the partialled-out residuals, controlling for endogenous selection of physicians, municipality and time fixed effects. Panel (b) shows the estimated first derivative, i.e. the marginal effect of increasing the physician coverage ratio on infant mortality. We find that physicians can strongly reduce infant mortality when coverage is sparse, but that the effect declines as coverage increases. Importantly, mortality effects are restricted to a specific interval of low coverage. After the coverage ratio reaches about 1.8 physicians per 1,000 of population, mortality effects subside. The estimated marginal effect is indistinguishable from zero for higher coverage ratios, in a region where
Figure 3: Semiparametric analysis

(a) Nonparametric fit

(b) Marginal effect

(c) Density

Notes: Figure (a) plots the partialled-out residuals of the infant mortality rate by physician density; accounting for the control function of the physician coverage ratio, individual and time fixed effects following the framework outlined by Baltagi and Li (2002). Observations with values outside the scale of the y-axis have been cropped from the scatterplot to improve exposition. The nonparametric fit was generated using local polynomial regression with a polynomial of degree 4, an Epanechnikov kernel function and a bandwidth of 1.3 chosen by Silverman’s rule-of-thumb. Shaded in grey are the 95% confidence intervals. Figure (b) plots the marginal effects by physician density, i.e. the first derivative of the above function for each level of the independent variable. Shaded in grey are the 95% confidence intervals. Figure (c) plots the distribution of the physician density to better illustrate sparse regions in the support.
the data is still dense (cf. panel (c)). Physicians most likely still influence morbidity, general health and quality of life in the population. However, after the population coverage ratio exceeds two physicians per 1,000, any remaining cases of infant mortality are unrelated to physician coverage and most likely medically difficult cases. Our results mirror the development of the industrialized world. In most developed countries, infant mortality rates have barely changed since the 1980s, when coverage ratios reached a comparable magnitude.

### 6.4 Robustness and specification checks

We conduct a series of robustness checks to show that our results are valid and not driven by alternative mechanisms or the choice of a specific model. The discussion in section 5 raises the point that a violation of the exclusion restriction could occur if districts with a higher rate of Jewish physicians evolve differently over time in a way that is related to mortality. For example, if the municipal population structure changes differentially for different levels of the instrument, population dynamics could also differ over time. Since we are restricting the outcome to mortality figures, any potential dynamic confounding mechanism will necessarily manifest in a municipality’s population dynamics. To address this issue, we replicate the main results from Table 1 in Table A2 in the appendix, adding the logarithm of population and population growth in $t - 1$ as covariates to control for population dynamics. The results replicate those in Table 1 almost exactly. In fact, precision improves for some of the estimates. The findings are robust to the inclusion of higher order polynomials as well. In addition, changes in population health may not occur instantaneously, but only with slight delay. We have tested this extensively, and our results are replicated almost exactly with a variety of alternative lag structures in the treatment variable.

An alternative mechanism that could explain our findings can be constructed if higher mortality is restricted to Jewish families. In that case, mortality effects may simply be caused by other discriminatory measures instead of the reduced quality of health care. Unfortunately, we are unable to distinguish mortality by population groups. However, it is extremely unlikely that the sizeable mortality effects are restricted to Jewish communities alone because of their disproportionately small population share. We test for this by repeating the analysis after dropping the 20% of municipalities with the most Jewish residents from our sample. Results remain qualitatively unchanged. Regarding other discriminatory measures, while the general environment grew considerably more hostile towards Jewish people after 1933, they still retained their citizenship status and full health insurance. Beginning in 1936, the *Nürnberger Gesetze* limited Jewish citizenship and marriage rights. After 1936, when preparations for war began, further policies essentially removed Jews’ citizenship rights gradually and targeted discriminatory measures against
anybody with Jewish heritage intensified substantially. Following the events of the Novemberpogrome in 1938, Nazi politics escalated from discrimination to systematic persecution, deracination and dispossession. Mass arrests without charges or proceedings commenced. The war started in 1939, the Holocaust began shortly after. For these reasons, we do not include data after 1936 in our analysis. The results are also robust to whether the year 1936 is included in the analysis or not.

Another concern is substitution, i.e. that health care demand is satisfied by visiting out-of-municipality physicians. If such behavior were present, it would likely bias our results towards zero. However, we believe that such bias is absent or marginal at best. Furthermore, the municipalities we consider are sufficiently large such that outside substitution is likely to be negligible in comparison. In our data, we only consider mortality of individuals registered within the municipality in question. From the limited vital statistics for children of outside residents we have, we cannot discern any noticeable trend in the regions were there are few Jewish physicians.

As discussed in sections 4 and 5, the distribution of some of the dependent variables raises the concern that the simple linear model may not be appropriate. We repeat our main analysis using the exponential model outlined in section 5. Results are given in Table A3. We choose a simple Poisson model for the naive specification (Table A3, first row), which is consistent even if the distribution were misspecified. Comparing the results, all findings from our main analysis carry through. The naive model does not offer conclusive results, suffering from positive selection. Results for the instrumental variable models are extremely similar. For most variables, the relative effects are almost identical to those obtained from the linear specification, indicating that the linear approximation for the mean works relatively well.

A related concern is that all dependent variables are expressed as ratios to describe relative incidence. This is common in the literature on health and development. We believe the advantages of this approach outweigh the disadvantages, meriting its application. The normalization allows for better interpretability and preserves comparability to standard measures used in other studies. As discussed previously, it reduces the distributional skewness of the unscaled count data (cf. Figure A4), improving the viability of standard linear models. However, if the treatment affects the denominator of the dependent variable as well, treatment effects are detected but could operate through a completely different mechanism. To mitigate this concern, all birth and population counts used in the denominator of the dependent variable are lagged by one period to rule out contemporaneous effects. Nevertheless, the results might still be driven by the denominator if there is serial correlation in these variables. We investigate this issue by repeating the main specifications from Table 1 using birth count as the outcome. In all specifications, the effect is either indistinguishable from zero or slightly negative. This implies that even if there were any change in the denominator, it biases the effect towards zero and the
mortality effect in the numerator has to offset the effect on the denominator.

7 Discussion

We analyze the effect of changes in the physician coverage on infant mortality and disease incidence in the population. Results indicate substantial negative effects. Increasing the coverage ratio from one to two physicians per 1,000 of population decreases infant mortality by about 23% relative to the pre-1933 level. We find similarly large effects for perinatal mortality rates and stillbirths. Mortality due to premature births and congenital debility, the largest cause of the remaining infant mortality in developed economies today, remains unaffected. Furthermore, we find that increasing health care coverage also reduces the mortality incidence of common diseases, specifically inflammatory bowel conditions, measles, influenza and bronchitis. From a medical perspective, these diseases can be treated and fatalities largely be prevented. In addition, we find that the effect of increasing coverage ratio on mortality is highly nonlinear. Mortality reductions are large in regions where coverage is sparse, but decrease quickly when coverage increases. Furthermore, they are only present in a narrow coverage region. After a density of about two physicians per 1,000 of population, mortality effects disappear.

These results have implications for a variety of policy issues. Obviously, training additional physicians is not the most cost-effective policy option to improve public health, when preventing sickness by improving sanitation and education regarding health-related behavior is a considerably cheaper and possibly more effective alternative. However, our results emphasize that preserving a level of baseline health care coverage is vitally important. Regional shortages and negative supply shocks can have severe consequences. Skilled outmigration has caused a shortage of physicians in many countries. Even developed economies are experiencing shortages in rural areas, a trend that has been increasing for years. The situation in many of the least-developed countries, where child mortality and health issues are already grave problems, is even more perilous. In much of Sub-Saharan Africa, current physician density ratios are often maintained by humanitarian aid and foreign health professionals. If these resources are withdrawn, e.g. due to budget cuts or conflict hazards, consequences for health care supply are severe. Our results imply that such sharp drops in care coverage are detrimental to public health. The Nazis’ dismissal of Jewish physicians resulted in a 10% drop in the coverage ratio. A simple back-of-the-envelope calculation suggests this lead to more than 2,200 additional infant deaths each year, even in a very conservative scenario.

Moreover, our analysis focuses on mortality, but population effects are not restricted to fatalities alone. Higher disease mortality is most likely caused by a general increase in disease prevalence among the population. Increased morbidity in an infant age will
reduce general well-being and can often lead to prolonged spells of ill-health and lower life expectancy. We are unable to capture morbidity effects with our analysis due to a lack of data, but they most likely exist. Quantifying these effects remains a task for future research.

Notes: Infant mortality variables are measured per thousand live births in t - 1, stillbirths per thousand total births in t - 1. Registered physicians are measured per thousand of population in t - 1. Included instruments are a full set of year and municipality dummies. Excluded instruments are given in the respective paragraph header if applicable. Standard errors clustered at the municipality level given in parentheses. *, **, *** denote significance at the 0.1, 0.05, 0.01 level respectively.

</tbody>
</table>

Notes: Results from exponential model instrumental variable estimation by GMM. Estimates are reported as incidence rate ratios, indicating the multiplicative change in the dependent variable given a unit increase in the physician coverage ratio. The null hypothesis in all tests is that the coefficient takes value one. Infant mortality variables are measured per thousand live births in \( t - 1 \), perinatal mortality per thousand total births in \( t - 1 \). Registered physicians are measured per thousand of population in \( t - 1 \). Included instruments are a full set of year and municipality dummies. Excluded instruments are given in the respective paragraph header if applicable. Standard errors clustered at the municipality level given in parentheses. *, **, *** denote significance at the 0.1, 0.05, 0.01 level respectively.
Figure A4: Comparison of count and reference-scaled distributions

(a) Raw counts

(b) Per reference population

Notes: Column (a) shows the distribution of the original unscaled counts, column (b) the distribution of the same variables scaled per reference population. Each row depicts the same base variable. All plots are based on the (largest) main estimation sample.
