Move a Little Closer?
Information Sharing and the Spatial Clustering of Bank Branches

Abstract
We study how information sharing between banks influences the geographical clustering of branches. We construct a spatial oligopoly model with price competition that explains why bank branches cluster and how the introduction of information sharing impacts clustering. Dynamic data on 59,333 branches operated by 676 banks in 22 countries between 1995 and 2012 allow us to test the hypotheses derived from this model. Consistent with our model, we find that information sharing spurs banks to open branches in localities that are new to them but that are already relatively well served by other banks. Information sharing also allows firms to borrow from more distant banks. (105 words)

Key words: Information sharing, branch clustering

JEL codes: D43, G21, G28, L13, R51
1. Introduction

Over the past two decades, banks across the world have adjusted their branch networks in response to regulatory changes, increased competition, and progress in information and communication technologies. Figure 1 illustrates the resulting time variation in the number of bank branches across a variety of countries. It also shows that more recently many American and European banks have pruned their branch networks in the aftermath of the Great Recession.

[Insert Figure 1 here]

What cannot be seen in Figure 1 is that these dynamics did not play out in a geographically uniform way within countries. Banks increasingly cluster together as they close branches in sparsely populated areas while opening new ones in economically stronger centers. For example, of the 600 UK branch closures between April 2015 and April 2016, over 90 percent were in areas with a below-median household income. In contrast, about two-thirds of all branch openings occurred in wealthier neighborhoods (Reuters, 2016). A similar trend can be observed in the United States, where branch clustering is mirrored by an increase in “banking deserts”: localities entirely devoid of bank branches (Morgan, Pinkovsky and Yang, 2016).¹

Despite this increase in geographic (spatial) clustering, hardly any theoretical or empirical research exists on the drivers of branch location. The scarce existing literature on the determinants of the spatial clustering of bank branches is either of a rational or behavioral nature (Deller and Sundaram-Stukel, 2012). Clustering is rational when locating near other banks generates external economies of scale or when the demand for banking services is spatially clustered itself (Brown, Guin and Kirschenmann, 2015). In contrast, behavioral explanations regard clustering as the result of “groupthink” or of banks following first-movers in an informational cascade.

¹ Nguyen (2015) finds that (merger-related) branch closures in the US cause prolonged declines in small-business lending and employment growth. These impacts are highly local and dissipate within six to eight miles.
model. Due to reputational concerns, bank managers may open a new branch in a neighborhood with pre-existing branches rather than in virgin territory. In line with such herding, Chang, Chaudhuri and Jayaratne (1997) find that branch openings follow existing branches even if this hurts the profitability of the new branch.

Both explanations for geographical branch clustering are hard to test empirically. For instance, it is challenging to evaluate current and expected credit demand across regions. Moreover, bank managers are compensated based on multiple criteria so that branch locational decisions are hard to evaluate separately. It is also problematic to directly measure and compare banks’ informational awareness.

The main contribution of our paper is to build a spatial oligopoly model that explains branch clustering behavior and that yields testable hypotheses about the impact of information sharing on the equilibrium level of clustering. To the best of our knowledge, we are the first to develop such a stylized model in which bank branch clustering arises in an intuitive way.

Our model revolves around an entrepreneur who needs credit to expand her business. She needs to visit a bank branch and talk to a loan officer to know whether she will get a loan or not. Suppose the probability of getting a loan from any local bank branch is 20 percent. Moreover, assume that the success probabilities across different bank branches are unrelated.\(^2\) If the entrepreneur visits a locality with only one bank branch, the probability of getting a loan is 20 percent. Yet, if another locality has six bank branches, then the probability of getting a loan is almost \(1 - (1 - 0.2)^6 \approx 74\) percent. Given this much higher probability, the entrepreneur will be tempted to visit the second locality. At the same time, the higher inter-bank competition in this locality will lower banks’ lending rates and profit margins. An important intuition of our model is therefore that while branch clustering increases the size of the local banking market (market-size effect), inter-bank proximity also implies more vigorous competition (price-cutting effect). If the first effect dominates, bank branches earn higher profits by locating closer to each other so that they can

\(^2\) We relax this assumption later on so that success probabilities are correlated across banks.
attract more clients. If the second effect dominates, banks will try to decrease competition by dispersing their branches geographically.

From this theoretical framework, we derive predictions about the impact of a reduction in information asymmetries between banks and borrowers on branch clustering. As information asymmetries increase with distance, geographical credit rationing makes it difficult for entrepreneurs to successfully apply for a loan at a branch that is further away (Petersen and Rajan, 2002; Hauswald and Marquez, 2006). Such distance constraints are less binding when banks can credibly share information about loan applicants, either voluntarily through private credit bureaus or mandatorily through public credit registries. In our model, information sharing therefore allows banks to lend to more distant entrepreneurs. We derive four testable hypotheses.

First, our model predicts that information sharing increases bank branch clustering and competition because banks can attract distant borrowers that were previously too opaque to lend to. Second, the model predicts that the likelihood that banks open a new branch in a locality where they already operate branches declines, because adding more branches to the same locality will not make it a more attractive ‘shopping’ destination. Third, information sharing spurs domestic banks (that rely on proprietary information) to cluster, while it helps foreign banks (that mainly use publicly available information) to expand into new localities. Finally, information sharing synchronizes different banks’ loan-approval decisions and hence dampens the market-size effect of clustering. Our model accordingly predicts that when information sharing becomes more effective, branch clustering gradually becomes less pronounced.

To empirically test our model, we use detailed bank branch data – geographical coordinates and the dates of establishment (and sometimes closure) of each branch – from 22 Eastern European countries. Our sample covers 59,333 branches that were active within the period 1995-2012. The data set further contains information on the banks that own these branches, which enables us to distinguish between branches of domestic versus foreign banks.
Eastern Europe constitutes a natural testing ground for our model because information asymmetries are pervasive while creditor rights remain relatively weak (Brown, Jappelli and Pagano, 2009). Moreover, many Eastern European countries institutionalized information sharing among lenders – either through a public credit registry or a private credit bureau – during our sample period. We use the introduction of such information-sharing regimes as country-level exogenous shocks that push banks towards a new clustering equilibrium. This setting can also provide insights into how bank clustering may respond in more developed banking markets to similar but slower improvements in borrower transparency.

In terms of methodology, we implement a differences-in-differences approach to evaluate the impact of the introduction of information sharing in some countries compared with other sample countries where information sharing had not yet been introduced. This strategy enables us to mitigate selection biases and, by allowing for country and time fixed effects, alleviates concerns about omitted variables.

By way of preview, we find that information sharing has a strong positive effect on bank branch clustering and that this impact is larger for domestic banks. Information sharing makes it more likely that banks open new branches in localities where they did not yet operate but where other banks were already present. The analysis of additional Kompass data on bank-firm relationships shows that, in line with a reduction in geographical credit rationing, information sharing allows firms to borrow from more distant banks. Lastly, we find that clustering becomes less pronounced over time in countries with more effective information sharing systems. All these findings are in line with our theoretical predictions.

This paper contributes to three strands of the literature. First, there is a clear lack of research that theoretically explains and empirically identifies the fundamental determinants of the physical location of bank branches. In contrast, a rich empirical literature exploits plausibly exogenous spatial variation in bank branches – reflecting historical ‘quirks’ or waves of financial deregulation – to identify the impact of bank
density on various outcomes. While useful for identification, one ought to bear in mind that outside of these specific settings, branches are unlikely to be spread quasi-randomly across space. Moreover, the limited literature that does investigate banks’ decisions concerning their branch network mainly focuses on the size of these networks rather than their geographical distribution. Our contribution is to develop a simple and intuitive framework in which banks rationally trade off the market-size and price-cutting effects of geographical clustering. We then test our model predictions in a rich international context, using the introduction of information sharing as country-level shocks that push banks towards a new clustering equilibrium.

Second, we add to the literature on the economic impacts of information sharing. Theoretical contributions explore how information sharing reduces moral hazard and adverse selection, improves loan quality, and lowers interest rates (Padilla and Pagano, 1997; 2000). On the empirical side, cross-country evidence indicates that information sharing is associated with more lending to the private sector, fewer defaults and lower interest rates (Jappelli and Pagano, 2002). Recent evidence suggests that (voluntary) private credit bureaus tend to be more effective than (mandatory) public registries in this regard (Martinez-Peria and Singh, 2014). Yet, it remains unclear exactly how information sharing affects bank behavior. We uncover an important mechanism: the central availability of borrower information leads to different equilibrium levels of branch clustering which may be associated with less spatial credit rationing.

---

4 Cerasi, Chizzolini and Ivaldi (2002) and Cohen and Mazzeo (2010) investigate the impact on competition of the size of branch networks. Temesvary (2015) shows theoretically and empirically that locational market power allows banks with larger branch networks to charge an interest-rate premium, while Coccorese (2012) incorporates branch decisions in a price competition model.

5 Van Cayseele, Bouckaert, and Degryse (1994) analyze theoretically the effect of sharing ‘negative’ borrower information about past defaults and ‘positive’ information about indebtedness on the number of branches per bank. Unlike our paper, the authors do not analyze the spatial distribution of branches.
Third, our findings add to the industrial organization literature on firm location. This literature asserts that customers trade off the utility they derive from products and the geographic distance to the firms where they can buy these products. As a result, firms have greater market power when they are closer to their customers. This literature starts with the Hotelling (1929) model where firms compete and price their products in geographic locations along a line of fixed length. Salop (1979) introduced a circle model on which firms are located and compete. Much sophistication has been built into such models over the years. Syverson (2004), for example, extends the Salop model to allow for heterogeneous producer costs and adds asymmetric information among producers about their production costs. Our assumptions are less stringent than those in the Salop (1979) model that is used extensively in the literature on bank competition (see Barros, 1999; Dell'Ariccia, 2001 and Kim, Lozano-Vivas and Morales, 2007). In our model, borrowers are uniformly distributed on a two-dimensional plane and banks can cluster in a locality (in contrast to the Salop model where banks are equidistant).

We proceed as follows. Section 2 introduces a simple spatial oligopoly model of branch clustering after which Section 3 describes our data. Section 4 then sets out our methodology and Section 5 reports the empirical findings. Section 6 concludes.

2. Theoretical model

2.1. Model intuition and construction

We develop a spatial oligopoly model to formalize the trade-off between the market-size and price-cutting effects of bank clustering. Specifically, we determine both the number of entrepreneurs who visit a locality to apply for credit (the market size) and the equilibrium loan rate prevailing in that locality (the price).7

---

6 We build on Konishi (2005) who models the spatial concentration of retail stores.

7 To ensure tractability, we assume that depositors put all their savings in the nearest bank branch and that the introduction of information sharing has no impact on the deposit market, a market much less affected by information asymmetries. Our focus on credit granting as a key banking activity is consistent with much of the literature (e.g., Stein, 2002; Berger and Udell, 2006; Hauswald and
In our model, both entrepreneurs and banking localities (towns or cities) are uniformly distributed across a two-dimensional plane. Each entrepreneur has identical project returns $r$ and wants to obtain a single loan for which she can apply by travelling to any locality with at least one bank branch. Entrepreneurs face a probability $p$ of not obtaining a loan when applying. This probability is correlated across branches with correlation $\phi$. We assume this correlation is the same for different localities.

Loan size is homogeneous across entrepreneurs and normalized to one. Entrepreneurs need to pay the commuting cost to their locality of choice and this cost equals the distance times a positive transportation cost coefficient $t$. In addition, entrepreneurs pay the equilibrium loan rate prevailing in this locality if they successfully obtain a loan there.

We assume there are two nearby bank localities $d$ and $s$ as well as a more distant bank locality $w$. Each entrepreneur visits at most one of these three localities to apply for a loan. We focus on branch clustering in locality $d$, treating as given the situation in localities $s$ and $w$.

The model consists of three stages. In Stage I, banks open a finite number of branches across localities on the two-dimensional plane. They cluster branches based on expected profits. In Stage II, entrepreneurs observe the locations of the branches and consequently receive a signal about the loan rate in each locality. They now decide, based on the expected return of borrowing in each locality, which locality to visit. The expected return depends on the distance to the locality (and the associated transportation costs), the probability of successfully applying for a loan there, and the interest rate in case the borrower receives credit. Each entrepreneur visits at most one locality: the one that in expectation gives the highest (positive) net return. If no locality yields a positive expected return, the entrepreneur does not apply for a loan.

Marquez, 2006, among many others). An interesting exception is Park and Pennacchi (2009) who concurrently model credit granting and deposit taking. We leave the spatial modelling of the information derived from observing checking account turnover, for example, for future research.

8 The local loan rate depends on the number of branches and hence the intensity of bank competition.
Critically, without information sharing among banks, information asymmetries between entrepreneurs and banks cause a discrete distance threshold beyond which the probability $p$ of an unsuccessful loan application is 1. Stated otherwise, due to geographical credit rationing entrepreneurs know for sure that they will be rejected when applying for a loan at branches beyond the distance threshold. Only below this threshold does the entrepreneur face the usual rejection probability $p < 1$ and trades off the higher transportation costs of more distant localities against the higher probability of receiving a loan (at a relatively low cost) in distant localities with more branches.

Finally, in Stage III of the model, bank branches in the same locality compete the loan rate down to a local equilibrium level. We assume that bank branches grant loans at zero marginal cost. We proceed by backward induction and start by Stage III. In locality $d$ with $k$ bank branches the equilibrium loan rate is:

$$i_d = i_0 + i_1/k$$  \hspace{1cm} (1)

Where $i_0$ stands for the minimum loan rate and $i_1$ is the oligopoly rent that banks can extract from nearby borrowers. With more bank branches, the equilibrium loan rate decreases in line with the price-cutting effect of branch clustering.

To determine the probability that a loan application is rejected, we start from the case of two bank branches. The probability of rejection at the first and the second branch both equal $p$ and the probability is correlated across branches with correlation $\varphi$. Because of this interdependence (different banks possess partially overlapping information about the same borrower), when a borrower gets rejected by one bank
branch, the rejection probability is also higher in another branch. Therefore, the joint probability of rejection at both branches equals (Gupta and Tao, 2010):

\[ \text{Prob}(2) = p \cdot p + \varphi \cdot \sqrt{p \cdot p \cdot (1 - p) \cdot (1 - p)} = p^2 + \varphi \cdot p \cdot (1 - p) \]  

(2)

In the case of three branches, we can compare the third branch with the first two branches while treating those first two as one unit. The joint probability of rejection at all three branches then equals:

\[ \text{Prob}(3) = p \cdot \text{Prob}(2) + \varphi \cdot \sqrt{p \cdot \text{Prob}(2) \cdot (1 - p) \cdot (1 - \text{Prob}(2))} \]  

(3)

Likewise, if there are \( k \) bank branches in locality \( d \), then the joint probability of rejection in locality \( d \) is:

\[ \text{Prob}(k) = p \cdot \text{Prob}(k - 1) + \varphi \cdot \sqrt{p \cdot \text{Prob}(k - 1) \cdot (1 - p) \cdot (1 - \text{Prob}(k - 1))} \]  

(4)

Then in Stage II, given the expected loan rates in each bank locality, an entrepreneur decides which locality to visit by maximizing the expected profit:

\[ EP_d = (1 - \text{Prob}(k))(r - i_d) - t \cdot R \]  

(5)

Where \( R \) is a threshold distance or radius between the borrower location and locality \( d \). If we assume that there is no overlap between localities \( d \) and \( s \), then the marginal entrepreneur should satisfy \( EP_d = 0 \) and we have:

\[ R_{no\ overlap}^* = \frac{(1 - \text{Prob}(k))(r - i_d)}{t} \]  

(6)
We can also generalize the model to allow for competition among nearby bank localities: that is, the market areas of locality $d$ and $s$ overlap. We assume that around locality $d$ there is an infinite number of localities $s$. The distance between all these localities $s$ and locality $d$ is $m$. Each locality $s$ has the same number of bank branches $j$.

The expected profit in locality $s$ is then:

$$E_P_s = (1 - Prob(j))(r - i_s) - t(m - R)$$ (7)

The equilibrium loan rate at locality $s$ equals:

$$i_s = i_0 + i_1/j$$ (8)

Assume that locality $d$ and $s$ are close enough so that the expected profit of visiting each locality is positive. The borrowers then compare the expected profit of both options and the marginal borrower is indifferent between locality $d$ and $s$:

$$E_P_d = E_P_s$$ (9)

This gives us the radius $R$ of locality $d$:

$$R_{overlap}^o = [(1 - Prob(k))(r - i_d) - (1 - Prob(j))(r - i_s)]/2t + m/2$$ (10)

Therefore, all entrepreneurs for whom the distance to $d$ is less than $R$ choose to go to locality $d$ to apply for a loan. In other words, the market area for locality $d$ encompasses a circle around locality $d$ with the above radius. If all bank branches in locality $d$ equally share the total market, then the market size of each branch in locality $d$ is:

$$S_d = (\pi * R^2)/k = [(1 - Prob(k))(r - i_d)/t]^2/k$$ (11)
The expected profit of each branch in locality $d$ is then:

$$E_d = S_d \ast i_d$$  \hspace{1cm} (12)

Finally, in Stage I, banks determine the clustering of their branches based on expected profits. They will not open a branch in locality $d$ if the expected profit is below the expected profit of opening a stand-alone branch in a new locality.

In our model, branch clusters increase an entrepreneur’s expected return for two reasons: a higher chance of getting a loan and loans being cheaper. These advantages may be (partially) offset if the locality is distant and transportation costs are high. There also exists a trade-off for the bank. On the one hand, branch clustering increases the local market because entrepreneurs prefer denser banking markets (the market-size effect). On the other hand, branch density and the associated competition reduce loan rates (the price-cutting effect). This trade-off determines the optimal level of clustering and makes the relationship between clustering and the expected profit of a branch follow an inverse U-shape. Denser branching initially leads to higher profits as the positive market-size effect dominates the negative price-cutting effect. After some optimum, however, opening another branch in a locality drives down profits as the price-cutting effect more than offsets the increase in market size.

In the absence of information sharing, entrepreneurs can only apply for a loan in nearby localities $d$ and $s$. Due to geographical credit rationing the loan-rejection probability in distant locality $w$ is 1. However, when information sharing is introduced the entrepreneur can also choose to apply for a loan in locality $w$. The establishment of information sharing thus increases competition in each banking locality and decreases the market size. Banks in nearby localities now have more incentives to cluster their branches in order to attract (or retain) borrowers who may be tempted to travel to a distant locality and apply there.

Assume there are $n$ branches located in distant locality $w$ and there is a strictly positive additional cost component $c$. These costs include higher expenses due to
long-distance travel as well as agency costs that result from the serious information
asymmetries between bank branches and very distant entrepreneurs. The marginal
entrepreneur who chooses the far-away locality \( w \) should hence satisfy:

\[
EP_n = (1 - Prob(n))(r - i_n) - c \geq 0
\]  

Note that with information sharing, the inter-branch correlation of the probability that
an entrepreneur cannot get a loan at any branch may also increase. This is because
different branches now have similar public information about a borrower. This
reduces the benefit of branch clustering and decreases the market-size effect.

If the transaction cost \( c \) is sufficiently small, then the fraction of entrepreneurs that
still visits bank locality \( d \) declines. The marginal entrepreneur who is indifferent
between going to locality \( d \) and locality \( w \) should satisfy:

\[
EP_d = EP_w
\]

This gives us the new radius \( R \), which should be strictly positive. This implies that
there are still some borrowers who visit bank locality \( d \) to get a loan:

\[
R_{info\_sharing}^* = [(1 - Prob(k))(r - i_d) - (1 - Prob(n))(r - i_n) + c]/t \geq 0
\]

Figure A1 in the Appendix shows the situation without overlap between the market
areas of locality \( d \) and nearby locality \( s \). The larger circle in light grey represents the
market area of locality \( d \) and \( s \) before information sharing, while the smaller dark
circle is the market area afterwards. The market size shrinks as some entrepreneurs –
those already at the outer margins of localities \( d \) and \( s \) – decide to apply for a loan in
locality \( w \). Figure A2 depicts the situation with competition among nearby localities.
The dashed line around locality \( d \) represents all the possible nearby localities \( s \).
2.2. Hypothesis development

We illustrate our simple model by some numerical illustrations. We assume that the probability of loan rejection is 70 per cent, both the minimal loan rate and the oligopoly rent is 2 percent, the project return is 10 percent, the transaction cost coefficient equals 1 per cent and the commuting cost of applying for a loan in the distant locality \( w \) is 6. There are 10 bank branches in this distant locality. We first assume that after the establishment of information sharing, the correlation among bank branches of a loan rejection stays at 0.2. Figure 2 shows the numerical results.

[Insert Figure 2 here]

The comparative statics in the top panel show that before the establishment of information sharing, banks cluster together until there are six branches in locality \( d \). The expected profit of each branch is still higher than the expected profit of operating alone. Adding a seventh branch would, however, push expected profit below the level that could be had when opening this branch in a new locality instead.

The bottom panel of Figure 2 shows that after the establishment of information sharing (which introduces competition from distant bank localities) branch clustering increases significantly to 16 (until the profit of operating alone is higher than with clustering). The introduction of information sharing reduces spatial credit rationing, increases competition, and decreases the market size. Banks in nearby localities now have more incentives to cluster their branches in order to attract (or retain) borrowers who may be tempted to travel to a distant locality and apply there.

Figure 3 shows the numerical results when nearby localities compete with each other. The comparative statics in the top panel show again that our model predicts a certain amount of bank clustering. According to the panel at the bottom of Figure 3, clustering increases from 4 to 14 branches in locality \( d \) once information sharing is introduced (we assume that the number of branches in locality \( s \) is 20 and that the
distance $m$ between locality $d$ and $s$ is $12$). That is, the increase in clustering happens regardless of whether there is overlap in nearby banking markets.

[Insert Figure 3 here]

In short, information sharing among banks impacts the equilibrium level of branch clustering as it eliminates the distance threshold beyond which entrepreneurs cannot successfully apply for loans. When borrower information is shared, entrepreneurs can in principle apply in each locality – as long as transportation costs are not prohibitive. Realizing this, banks start to cluster in order to attract more distant entrepreneurs that are in search of deeper credit markets in which they can apply for a loan from a wider variety of banks. This yields our first testable hypothesis:

**HYPOTHESIS 1:** *After the introduction of information sharing, different banks increasingly cluster their branches in the same localities.*

Our model also predicts that banks exploit the opportunities of sharing borrower information by extending their branch network to localities where adding a branch of their own increases the number of different banks that entrepreneurs can choose from. In contrast, adding more branches of the same bank in a locality where this bank is already present does not make this locality a more attractive ‘shopping’ destination for (distant) entrepreneurs because loan rejection rates are perfectly correlated among branches of the same bank. That is, if an applicant gets rejected by a branch of Bank A it will get rejected by *all* branches of Bank A in the same locality. This impact is more important after the introduction of information sharing when attracting and retaining borrowers becomes more vital. Our second hypothesis is therefore:

**HYPOTHESIS 2:** *After the introduction of information sharing, banks are more likely to open new branches in localities with no (or few) pre-existing own branches.*
Third, our model implies that information sharing can affect domestic and foreign banks differently if these banks rely on other lending technologies. Domestic banks often rely on long-term lending relationships during which they exploit proprietary borrower information whereas foreign banks focus on transactional lending based on publicly available information (Mian, 2006 and Beck, Ioannidou, and Schäfer, 2017). This means that in the absence of information sharing, distance thresholds due to informational asymmetries can bind more for domestic banks. In our model, this amounts to borrowers facing a higher agency cost $c$ when applying at a domestic bank branch as compared with an equidistant foreign branch (recall that $c$ comprises both agency and travel costs). The introduction of information sharing then affects domestic banks more because the overall reduction in $c$ is larger, leading to an increase in domestic bank clustering in particular.

Figure 4 illustrates this prediction with numerical results. We assume that prior to information sharing the cost of long-distance lending was higher for domestic (6.5) than for foreign banks (6.2). This reflects that relationship lending by domestic banks involves higher distance-related agency costs. With information sharing, the cost of screening distant clients is equalized at 6 as both bank types can now use the credit registry or bureau. This change is larger for domestic banks (-0.5) than for foreign banks (-0.2). The model shows accordingly that the clustering response is stronger for domestic banks (both with and without overlap among nearby localities). Our third hypothesis is therefore:

**HYPOTHESIS 3:** *The impact of information sharing on bank clustering is stronger for domestic banks.*

[Insert Figure 4 here]

Finally, the impact of information sharing on branch clustering depends on how effective the information-sharing system works. We already know that information
sharing increases the correlation between different banks’ loan decisions. As a matter of fact, the effectiveness of information sharing and related loan decision correlations can be so high that this induces a negative market-size effect and a decrease in bank branch clustering.

To see this in our calibration exercise, we gradually increase the correlation from 0.2 to 0.3 and compare equilibrium clustering (Figure 5). The horizontal axis shows the correlation among banks in loan rejection decisions (a higher correlation indicates a more effective information-sharing system) and the vertical axis shows bank branch clustering in equilibrium. We indeed observe that when lending decisions across banks become increasingly correlated, there is a decline in the market-size effect and therefore in branch clustering. Our fourth and final hypothesis is therefore:

**Hypothesis 4**: Information sharing increases branch clustering but this relationship turns negative once the effectiveness of information sharing – as measured by the interbank correlation in lending decisions – becomes sufficiently high. The relationship between the effectiveness of information sharing and branch clustering consequently displays an inverse U-shape.

[Insert Figure 5 here]

### 3. Data

Table 1 provides summary statistics of our dependent variables (branch data) and independent variables. Appendix Table A1 provides all definitions.11

#### 3.1. Branch data

To test our hypotheses, we require time-varying data on branch locations for countries in which information sharing – either through a public credit registry or through a private credit bureau – is introduced at different points in time. We therefore collected

---

11 Appendix Table A2 contains a correlation matrix of all variables.
information on the geographical coordinates of 59,333 branches operated by 676 banks across 22 emerging European countries. These data paint a precise and gradually changing picture – reflecting branch openings and closures – of the banking landscape during the years 1995-2012. Figure 6 shows the geographical branch distribution in these countries at the start and the end of our sample. During our sampling period, bank started to gradually cluster more as indicated by a 17.9 percent increase in the cross-locality Herfindahl-Hirschman index.

[Insert Figure 6 here]

Appendix Table A3 summarizes the number of branches that opened or closed by year and country: 33,716 (1,365) branches opened (closed) during our sample period. Many new branches were established during 2001-07, a period of rapid credit growth. The expansion of branch networks slowed down after the global financial crisis when fewer branches opened while branch closures (rare before the crisis) accelerated.

For each branch, we know the identity of the parent bank. By merging our data with the bank ownership data in Claessens and Van Horen (2014) we can distinguish between branches owned by foreign and domestic banks. A bank is classified as foreign if at least half of its equity is in foreign hands. We further distinguish between greenfield foreign banks (de novo banks established from scratch) and take-over banks that were formed when a foreign bank acquired a domestic one.

We take the 33,716 branch openings during our sample period as our main unit of observation. This allows us to test whether the introduction of information sharing encouraged banks to open branches in different types of localities. Table 1 shows that

---

12 A team of consultants with extensive banking experience collected the data by contacting banks or downloading data from bank websites. This data-collection exercise was part of the second Banking Environment and Performance Survey (BEPS II). For more information, see Beck, De Gryse, De Haas and Van Horen (2018). See also: http://www.ebrd.com/what-we-do/economics/data/banking-environment-and-performance-survey.html.

13 Our data set contains 59,333 branches (owned by 676 banks) of which 33,716 (owned by 532 banks) opened during 1995-2012. The remaining 144 banks did not open branches during this period.
approximately half of all branch openings took place when a country had a credit registry or bureau in place (*Information sharing*). 44 per cent of all branch openings were by a foreign bank and about a third of these were by greenfield foreign banks.

[Insert Table 1 here]

Our main dependent variables capture the clustering of banks across countries and over time. *No. branches all banks* measures the number of pre-existing bank branches in the proximity of a newly opened branch. For this and all other dependent variables, we use two methods to match a new branch with all nearby existing branches. First, we draw circles with a 2 or 5 km radius around the geo-coordinates of the new branch and count the number of existing bank branches within that circle. Second, we count the number of existing branches within the same locality (town or city) as where the new branch is located. Table 1 shows that the median new branch is surrounded by 17 pre-existing branches within a 2-km radius, 23 branches within a 5-km radius, and 25 branches within the same locality.

*Branch same bank* is a dummy that indicates whether the bank that opens a new branch already operated one or more branches in the same area (circle or locality). The probability of pre-existing branches of the same bank being present is 33 (37) per cent when the surrounding area is measured as a circle with a 2 km (5 km) radius and 38 per cent when branches are matched by locality. While the median number of pre-existing branches is zero, there is wide variation and the average number is three.

Lastly, we measure local credit market concentration by constructing a Herfindahl Hirschman Index (HHI) for each circle or locality around a new branch:

\[ HHI_i = \sum_{i=1}^{N} s_i^2 \]  

(16)

Where \( s_i \) stands for the market share, measured in branches, of bank \( i \) in the market and \( N \) is the number of banks.
3.2. Data on information sharing

Data on the introduction of information-sharing regimes are from the World Bank Doing Business database, the EBRD, and on-line sources. Appendix Table A4 shows that during 1995-2012, fifteen countries introduced a public credit registry and eighteen a private credit bureau. There exists substantial variation in the timing of the introduction of information sharing which is helpful for our empirical identification.

The upper chart in Figure 7 shows the average number of pre-existing branches of the same bank around newly opened branches in the four years before and the four years after the establishment of information sharing at $t=0$. In line with our second hypothesis, after the introduction of information sharing, new branches open in localities where banks have fewer pre-existing branches of their own (that is, banks spread out their own branch network). The second and third chart show that, in line with our first hypothesis, these new branches tend to cluster in more competitive markets (with more existing branches from other banks and hence a lower HHI).

[Insert Figure 7 here]

Lastly, we measure the quality of the information-sharing regime in a country by means of the World Bank Doing Business credit information index. The index ranges from 0 to 6 and reflects rules and practices affecting the coverage, scope and accessibility of credit information from either a public credit registry or a private credit bureau (higher values indicate more effective information sharing). Among our 22 countries the average value of Quality information sharing is 1.45 but there is wide variation with a standard deviation of 2.16 (Table 1).

---

14 A score of 1 is assigned for each of six features: (1) Both positive credit information (outstanding loan amounts and on-time repayments) and negative information (late payments and defaults) are distributed; (2) Data on both firms and individuals are distributed; (3) Data from retailers, utility companies, and financial institutions are distributed; (4) More than two years of historical data are distributed; (5) Data on loan amounts below 1 percent of income per capita are distributed; and (6) By law, borrowers have the right to access their data in the largest credit bureau or registry.
4. Methodology

To test our hypotheses, we apply a differences-in-differences framework with multiple groups (countries) and time periods (Wooldridge, 2007). To test Hypothesis 1, we estimate the following benchmark model:

$$N_{ijct} = \alpha_c + \alpha_t + \beta_1 T_{ct} + \epsilon_{ijct}$$ (17)

Where $i$ indicates a new bank branch; $j$ the locality in which the new branch opens (circle or town/city); $c$ indicates the country and $t$ refers to the year. $N_{ijct}$ is the number of pre-existing branches when branch $i$ opens in locality $j$ (No. of branches all banks). $T_{ct}$ (Information sharing) is a dummy equal to 1 if banks in country $c$ share borrower information in year $t$. $\alpha_c$ and $\alpha_t$ are country and year fixed effects. According to our model, $\beta_1$ is expected to be positive as the introduction of information sharing induces bank branches to cluster so as to attract more borrowers.

We also run this model with the locality-level HHI index on the left-hand side ($HHI_{ijct}$). We then expect $\beta_1$ to be negative as smaller information asymmetries due to information sharing mean that new branches tend to open in more competitive local markets with a lower pre-existing HHI.

To test Hypothesis 2, we measure the number of existing branches of the same bank in the locality where a branch opens (No. branches same bank): $N_{ijct}^{own}$. We also construct a dummy version of this variable ($D_{ijct}^{own}$) that is equal to 1 if $N_{ijct}^{own} > 0$ and 0 otherwise (Branch same bank). We run the following regression model:

$$N_{ijct}^{own} = \alpha_c + \alpha_t + \beta_1 T_{ct} + \epsilon_{ijct}$$ (18)

According to our model, information sharing makes banks less likely to open new branches in localities where they already operate branches themselves. We therefore expect $\beta_1$ to be negative.
To examine whether information sharing differentially impacts domestic and foreign banks, we run interaction regressions. Assuming that domestic (foreign) banks are more oriented towards relationship (transaction) lending, we expect domestic banks to be more affected by the introduction of information sharing and therefore have more incentives to cluster. Let $F_i$ be a dummy equal to 1 if a branch belongs to a foreign bank. The sum of $\beta_1$ and $\beta_2$ is now the treatment effect for foreign banks:

$$N_{ijct} = \alpha_c + \alpha_t + \beta_1 T_{ct} + \beta_2 F_i + \beta_3 T_{ct} * F_i + \epsilon_{ijct}$$ (19)

Lastly, we investigate to what extent the effectiveness of information sharing matters for branch clustering (Hypothesis 4). The time-varying variable $Quality_{ct}$ measures the rules and practices affecting the accessibility, coverage, scope and quality of credit information available through information sharing ($Quality \text{ information sharing}$). Augmenting the base regression (1) with this variable renders:

$$N_{ijct} = \alpha_c + \alpha_t + \beta_1 T_{ct} + \beta_2 \cdot Quality_{ct} \cdot F_i + \epsilon_{ijct}$$ (20)

Note that $Quality_{ct}$ is only available for country-years in which banks exchange borrower information (i.e., $T_{ct} = 1$). The value equals zero if there is no information sharing in a specific year and country. Based on our model we expect $\beta_1$ ($\beta_2$) to be positive (negative). Very effective information sharing ensures that all banks have access to the same comprehensive information about loan applicants. This increases the inter-bank correlation in loan decisions and dampens the market-size effect of clustering. After all, it becomes less attractive for borrowers to travel to (distant) localities with many branches (as the probability that a loan application gets rejected at each branch becomes very similar). In the extreme case, when all branches share all information and process these data in the same way, there is no difference between having just one branch or having many branches in a locality. Increasingly effective information sharing therefore starts to dampen clustering at one point (all else equal).
5. Empirical results

5.1. Baseline results

Table 2 presents our baseline results (cf. equations (17) and (18)). For each dependent variable – No. branches all banks, Branch same bank, No. branches same bank, and $HHI$ – we show three regression outcomes for different proxies of the dependent variables. In the first two regressions, we match newly-opened branches with all surrounding pre-existing branches within a 2-km or a 5-km radius. In the third specification, we match new branches with all existing branches in the same locality. All regressions include country and year fixed effects.

In line with our first hypothesis, columns 1-3 show that once a country introduces information sharing, banks start to open new branches in localities with more pre-existing branches compared to countries where information sharing has not (yet) been introduced. Our results are qualitatively similar when matching new branches with existing branches in a 2 (5) km radius (columns 1 and 2) or within the same locality (column 3). The impact of a credit registry is economically significant: column 3 shows that once information sharing is introduced, banks choose to locate new branches in towns and cities that have 55 more pre-existing bank branches. This is a large effect given that the average locality in our data set contains 129 branches.

In contrast, and in line with hypothesis 2, columns 4 to 9 show that information sharing induces banks to open new branches in localities where they have fewer existing branches of their own. This effect is again sizable: after the establishment of information sharing, banks are 11 percentage points less likely to locate a new branch in cities where they already own one or more branches of their own (column 6). The number of pre-existing own branches is reduced by almost 3 (the average is 4).

Lastly, columns 10 to 12 reveal that after the introduction of information sharing banks start to open new branches in less concentrated markets – as indicated by a lower HHI index. This aligns with our first result.

[Insert Table 2 here]
5.2. **Heterogeneous impacts by bank type**

Not all banks may be equally affected by information sharing. To analyze such heterogeneity, we interact in Table 3 the information sharing variable with dummies that identify foreign banks (in line with eq. (19)). The first three columns of Table 3 indicate that while information sharing affects the clustering of all banks, the impact is significantly stronger for domestic banks. For instance, after the establishment of information sharing, domestic banks tend to open new branches in localities with 74 more existing branches (compared with the situation before information sharing). This number is only 34 (74.39 - 40.88) for foreign banks.

The first three columns of Table 3 also show that before the introduction of information sharing, foreign banks opened branches in localities with more pre-existing branches. That is, compared to domestic banks, foreign banks typically added branches to well-established local banking markets rather than venturing into new territory. A possible explanation is that compared to domestic banks, foreign banks have built up less information about domestic clients and therefore mimic the locational choices of domestic competitors. This effect is economically significant: foreign banks locate new branches in cities with 84 more pre-existing branches. The introduction of information sharing therefore partially levels the playing field between foreign and domestic banks: it allows foreign banks to open branches in underserved markets that they previously avoided.\(^{15}\)

Lastly, columns 4-9 in Table 3 show that with information sharing foreign banks tend to open branches in new localities where they had no or few branches before.\(^{16}\) Prior to information sharing, foreign banks were more likely than domestic banks to

\(^{15}\) In Appendix Table A5 we take this analysis one step further by distinguishing between greenfield and take-over foreign banks. As expected, the introduction of information sharing is especially beneficial to greenfield foreign banks: these relatively young and inexperienced banks cluster less after the introduction of information sharing and can spread out their branch networks more widely.

\(^{16}\) We also test this at the locality level as shown in Appendix Table A6. Specifically, we generate a dummy, \textit{Foreign bank existence}, that is equal to ‘1’ if there is at least one foreign bank branch in a locality in a specific year; and ‘0’ otherwise. The results show that after the introduction of information sharing, localities are more likely to have foreign bank branches, which is in line with the prediction that information sharing helps foreign banks in particular to expand into new localities.
cluster their own branches together but, again, the registry appears to allow foreign banks to geographically spread out their branch networks. After the establishment of information sharing, foreign banks are 4 percentage points less likely than domestic banks to open new branches in a locality with prior branches of their own.

[Insert Table 3 here]

5.3. Heterogeneous impacts by effectiveness of the information-sharing regime

Table 4 assesses our fourth hypothesis that in countries with particularly effective information sharing, branch clustering will gradually level off. More specifically, our model predicts that the market-size effect of clustering declines when the inter-bank correlation in loan-rejection probabilities increases. The intuition is that banks receive increasingly similar public information about applicants and are therefore more likely to make the same lending decisions. Note that only in countries with information sharing in place, we can calculate the variable Quality information sharing (in countries without information sharing, this variable is zero).

The first three columns in Table 4 show that, in line with our fourth hypothesis, the presence of information sharing leads to more branch clustering but that this increase becomes smaller for more effective registries. The results in column 3 indicate that an improvement of the registry quality by 2 points (out of 6, about one standard deviation) reduces branch clustering due to information sharing from 51 to 38 pre-existing branches per locality. We also construct a dummy, Better information sharing, that equals one if the quality of information sharing index ranges between 4 and 6, and zero otherwise. The results in the last three columns indicate that although information sharing results in more bank branch clustering, this effect becomes smaller or even reverses in countries with very effective information-sharing systems.

---

17 We only show results for the dependent variable No. branches all banks as this is the only variable for which our theoretical model yields a clear prediction for the sign of the coefficient.
5.4. Robustness and placebo tests

We subject our results to various robustness and placebo tests. First, one may worry that the introduction of information sharing in a country is endogenous as it reflects unobservable national circumstances that also bear directly on branch clustering. We absorb any time-invariant unobservable variation through country fixed effects, and region-wide time variation through year fixed effects. However, we cannot control for unobservable country-specific and time-varying variables. We therefore instrument the introduction of information sharing in a country and year with the percentage of all neighboring countries that introduced information sharing in the past five years (Martinez Peria and Singh, 2014). This instrument builds on the notion that financial reforms tend to converge regionally (Abiad and Mody, 2005). The exclusion restriction is that the introduction of information sharing in nearby countries only has an impact on domestic bank clustering via an increase in the probability that information sharing is introduced domestically as well.

Table 5 reports our IV outcomes. The first stage shows a strong and positive correlation between the introduction of information sharing in neighboring countries in the recent past and the introduction of a credit registry or bureau in the country of observation. Both the Cragg-Donald Wald F-statistic and the Kleibergen-Paap F-statistic indicate that our instrument is strong. Moreover, the second-stage estimates are qualitatively very similar to our OLS baseline results, suggesting that endogeneity in the introduction of information sharing is not driving our results.

Table 6 reports a battery of robustness tests related to the clustering of standard errors. Our baseline approach throughout the paper is to report robust standard errors. Table 6 shows that our results hold when clustering standard errors by bank (columns 1-3),
country (columns 4-6), or year (columns 7-9). Moreover, our results go through when clustering standard errors by bank*locality (each bank can have several observations in the same locality if it opens branches in that locality at different points in time, columns 10-12), by country*year (columns 13-15), or by bank*year (columns 16-18).

[Insert Table 6 here]

Finally, Table 7 reports a placebo test. For each year, we keep the same number of information sharing introductions but instead of using the actual event countries, we assume that information sharing was introduced in another country group of the same size. This placebo country group is chosen randomly out of the total set of countries that at that point in time had not (yet) introduced information sharing. This approach thus preserves the cross-country trend in information sharing introductions, but randomly reallocates these events from the actual to placebo countries. We repeat this random reallocation 500 times and report the average estimation results. As expected, the results disappear in this placebo test, suggesting that it is unlikely that our results reflect unobservable characteristics or linear trends.

[Insert Table 7 here]

5.5. Extension: Information sharing and geographical credit rationing

An important model prediction that we have not yet been able to test with our branch-level data is that the introduction of information sharing reduces spatial credit rationing: firms will be able to borrow from more distant bank branches. To empirically test this prediction, we merge our branch data with information from the Kompass database on firm-bank relationships. Kompass provides firm-level data including address, industry, and – critically for our purposes – the primary bank relationship(s) (see also Giannetti and Ongena, 2012 and Ongena, Peydró and Van Horen, 2015). We have these data for the years 2000 and 2005.
We collect the geographical coordinates of the firms in Kompass based on their name and address and identify the name of their primary bank. We then match each Kompass firm to all the branches from their primary lender (using BEPS II information) and calculate the distance from the firm to each of these branches. We then assume that firms borrowed from the nearest branch of their primary bank and use this nearest distance as the *Firm-branch distance* in kilometers.

Of all the countries in Kompass, there are four that introduced information sharing between 2000 and 2005 and that are also included in our BEPS data: the Czech Republic, Estonia, Latvia, and Poland. Because the bank information in Kompass and in BEPS can only be matched poorly for Estonia and Latvia, we focus on the Czech Republic and Poland. These countries introduced information sharing in 2002 and 2001, respectively. We also include two countries that did not introduce information sharing between 2000 and 2005. There are four such BEPS countries (Croatia, Hungary, Slovakia, and Ukraine) but because the matching of bank information is very poor for Slovakia and Ukraine we focus on the first two. We thus compare the change in firm-branch distance between 2000 and 2005 in two countries that introduced information sharing during this period (the Czech Republic and Poland) with the change in firm-branch distance in two similar countries that did not (Croatia and Hungary). The final merged data set contains 9,504 and 4,980 firm records in 2000 and 2005, respectively, across these four countries.

The left panel of Table 8 shows summary statistics and a two-sample t-test with unequal variances. In the countries that introduced information sharing between 2000 and 2005 (the Czech Republic and Poland), firms on average borrow from more distant bank branches in 2005 than in 2000 (2 km and 8 km further, respectively, for the Czech Republic and Poland). In contrast, firms do not borrow from more distant branches in the two comparator countries that did not introduce information sharing during this period (Croatia and Hungary). We also test this more formally in a differences-in-differences regression framework (right panel of Table 8). We find that after the introduction of information sharing, firms borrow from branches that are
almost 3 km further away as compared to firms in countries that did not introduce information sharing during the same period.

These additional results indicate that information sharing reduces spatial credit rationing and enables firms to borrow from bank branches that were previously too far away. These findings are in line with, and thus support, our theoretical assumption that the introduction of information sharing reduces spatial credit rationing and enables borrowers to successfully approach more distant bank localities.

[Insert Table 8 here]

6. Concluding remarks
It is well known that branches of different banks tend to cluster spatially. Yet, to date there exists surprisingly little theoretical and empirical research on the drivers of this phenomenon. Our contribution is to use the introduction of information sharing regimes as plausibly exogenous shocks that shift the relative advantages and disadvantages of branch clustering. We then observe how these shocks play out at a very disaggregated level (that of individual villages, towns, and cities) across a variety of countries.

We start by building a simple spatial oligopoly model of branch clustering. The model focuses on the trade-off between the market-size effect and the price-cutting effect of branch clustering. It predicts that the establishment of information sharing will stimulate clustering due to an increase in competition from far-away bank branches. The model also predicts that after the introduction of information sharing, banks will be less likely to open additional branches in locations where they already have a presence. Finally, our model indicates that more effective information sharing systems will gradually dampen bank branch clustering.

In the empirical part of the paper, we then test these theoretical predictions by exploiting dynamic information on the geographical locations of bank branches. We find that the establishment of information sharing has a significantly positive impact
on bank clustering and that this impact is larger for domestic banks. We also show 
that after the establishment of information sharing banks are more likely to locate new 
branches in “virgin” localities (that is, where they did not have a branch presence yet). 
As a result of these changes, the average firm is able to borrow from more distant 
bank branches. Finally, we establish that countries with more efficient credit 
information sharing systems start to exhibit less pronounced bank clustering. 

Taken together, our results show that branch clustering is a function of the public 
availability of trustworthy borrower information. When such information is more 
broadly available, banks – especially new players such as foreign-owned banks – can 
expand their branch network to new localities that they would previously have 
avoided. At the same time, it becomes more important for banks to cluster together as 
a higher local variety of banks makes it easier to attract distant customers. Together, 
these effects mean that banking markets become more homogenous in terms of 
composition – as they are served by the same banks that now operate across the 
country – but less homogenous in terms of size. While the public availability of 
information sharing leads to further clustering of banks in well-served locations, other 
(smaller) locations may lose out as access to credit deteriorates further. Assessing the 
real-economic impacts of such spatial variation in access to credit due to information 
sharing is a promising avenue for further research.

**Table 4**

**Quality of Information Sharing and Bank Branch Clustering**

This table reports OLS regressions to estimate the impact of the introduction of information sharing and of the quality of this information sharing system on subsequent bank branch clustering. The dependent variables measure the pre-existing branch structure in each locality where a new bank branch is opened. Table A1 contains all definitions and Table 1 the summary statistics for each variable. Robust p-values are reported in parentheses. ***, **, * correspond to the 1%, 5%, and 10% level of significance, respectively.

Table 5
Robustness: IV framework

This table reports IV regressions to estimate the impact of the introduction of information sharing on subsequent bank branch clustering. The instrument in the first stage is the percentage of neighboring countries that introduced information sharing in the previous five years. Table A1 contains all definitions and Table 1 the summary statistics for each variable. Robust p-values are reported in parentheses. ***, **, * correspond to the 1%, 5%, and 10% level of significance, respectively.

### Table 7

**Placebo Test: Random Introduction of Information Sharing Across Countries**

This table reports placebo OLS regressions to estimate the impact of the introduction of information sharing on subsequent bank branch clustering. The dependent variables measure the pre-existing branch structure in each locality where a new bank branch is opened. For each year we keep the actual number of credit registry introductions but instead of using the actual countries that introduced information sharing in that year, we use the same number of placebo countries (randomly picked from the total set of countries that in that year had not (yet) introduced information sharing). We repeat this randomization and estimation 500 times and present average results. Table A1 contains all definitions and Table 1 the summary statistics for each variable. Robust p-values are reported in parentheses. *, **, *** correspond to the 1%, 5%, and 10% level of significance, respectively.

Year Fixed Effects | Yes |
| Country Fixed Effects | Yes |
These charts show the development of the total number of bank branches by country. If a foreign bank has several branches in a host country then these are counted as a single branch in the case of European countries (in line with ECB methodology). Source: FDIC and ECB.
Figure 2

Branch Clustering after the Establishment of Information Sharing 

No Overlap Among Bank Localities

This figure presents comparative statics based on a calibration of our theoretical model that assumes no overlap among nearby bank localities. We assume that the probability of loan rejection is 70 per cent; the minimal loan rate is 2 percent; the oligopoly rent is 2 percent; the project return is 10 per cent; the commuting cost coefficient is 1 per cent; the correlation among bank branches of the loan-rejection probability is 0.2; and the commuting cost of applying for a loan in a distant locality is 6. There are 10 bank branches in the distant locality $w$. The vertical axis presents the expected profit of each bank branch and the horizontal axis shows the number of bank branches. Darker (lighter) shades indicate that the expected profit of opening a new branch in locality $d$ is larger (smaller) than the expected profit (shown by the first column at the very left) of opening a new branch in a new locality without pre-existing branches. Before the establishment of information sharing, banks cluster together until there are 6 branches in locality $d$. The expected profit of each of these 6 branches is still higher than the expected profit of operating alone (which is just above 40). Adding a 7th branch would, however, push expected profit below the profit that could be had when opening that additional branch in a new locality instead. After the introduction of information sharing (which introduces competition from distant bank localities) branch clustering increases significantly to 16 (until the profit of operating alone is higher than clustering).
Branch Clustering after the Establishment of Information Sharing
Overlap Among Bank Localities

This figure presents comparative statics based on a calibration of our theoretical model that assumes overlap among nearby bank localities. We assume that the probability of loan rejection is 70 per cent; the minimal loan rate is 2 percent; the oligopoly rent is 2 percent; the project return is 10 per cent; the commuting cost coefficient is 1 per cent; the correlation among bank branches of the loan-rejection probability is 0.2; and the commuting cost of applying for a loan in a distant locality is 6. There are 10 bank branches in the distant locality $w$. The number of bank branches in locality $s$ is 20 and the distance between locality $d$ and $s$ is 12. The vertical axis presents the expected profit of each bank branch and the horizontal axis shows the number of bank branches. Darker (lighter) shades indicate that the expected profit of opening a new branch in locality $d$ (shown by the first column at the very left) is larger (smaller) than the expected profit of opening such a branch in a new locality without pre-existing branches. Before the establishment of information sharing, banks cluster together until there are 4 branches in locality $d$. The expected profit of each of these 4 branches is still higher than the expected profit of operating alone (which is just above 40). Adding a 5th branch would, however, push expected profit below the profit that could be had when opening that additional branch in a new locality instead. After the introduction of information sharing (which introduces competition from distant bank localities) branch clustering increases significantly to 14 (until the profit of operating alone is higher than clustering).
This figure analyzes the difference between the impact of information sharing on domestic and foreign banks. Information sharing reduces the cost of screening distant borrowers from 6.5 to 6 for domestic banks and from 6.2 to 6 for foreign banks. The introduction of information sharing therefore induces more branch clustering by domestic banks than by foreign banks. Dark (light) bars show results without (with) overlap among nearby localities.
This figure shows the declining equilibrium level of branch clustering when the inter-branch correlation of loan-rejection rates increases as information sharing systems become more effective (from 0.2 to 0.3). Bank branch clustering decreases when the quality of information sharing increases (with higher correlation among banks in loan rejection decisions).

**Figure 5**

**Quality of Information Sharing**

This figure shows the declining equilibrium level of branch clustering when the inter-branch correlation of loan-rejection rates increases as information sharing systems become more effective (from 0.2 to 0.3). Bank branch clustering decreases when the quality of information sharing increases (with higher correlation among banks in loan rejection decisions).

- **No overlap among nearby localities**
- **Overlap among nearby localities**
Figure 6
Distribution of Localities with Bank Branches in 1995 and in 2012

Panel A. This map plots all localities in our dataset with at least one bank branch in 1995. Source: BEPS II survey.

Panel B. This map plots all localities in our dataset with at least one bank branch in 2012. Source: BEPS II survey.
The first two charts show the trend in the number of pre-existing branches of the same bank and all banks, respectively, within a 2 km radius around newly opened branches in the four years before and the four years after the establishment of information sharing at t=0. The third chart shows the same for the HHI index in the 2 km around newly opened branches. Table A1 contains all variable definitions.
## Appendix

### Table A1

<table>

### Table A4

**Introduction of Information Sharing**

This table provides an overview of the introduction years of public credit registries and private credit bureaus in our 22 sample countries. N.a.: No credit bureau or registry has as yet been introduced in this country. Source: World Bank Doing Business Database, EBRD and various publications and websites.

### Table A5

**Information Sharing and the Geographical Clustering of Greenfield Foreign Bank Branches**

This table reports OLS and probit (columns 4-6) regressions to estimate the impact of the introduction of information sharing on subsequent bank branch clustering by greenfield foreign banks. Table A1 contains all definitions and Table 1 the summary statistics for each variable. Robust p-values are reported in parentheses. ***, ***, * correspond to the 1%, 5%, and 10% level of significance, respectively.

### Table A6

**Information Sharing and the Geographical Expansion of Foreign**

This table reports OLS regressions to estimate the impact of the introduction of information sharing on the geographical expansion of foreign bank branches. In column 1, the sample includes all localities in all the years, even those with 0 bank branches. Column 2 excludes these 0 bank branches locality-year observations. Table A1 contains all definitions and Table 1 the summary statistics for each variable. Robust p-values are reported in parentheses. ***, **, * correspond to the 1%, 5%, and 10% level of significance, respectively.
