• In our life-cycle consumption-saving model, Δ can be as large as 1% of *total* lifetime consumption.

• Survival ambiguity is **highly regressive**: cost to the poorest quintile is 4 times larger than the cost to the richest quintile.

• Why? The poor rationally believe there is a strong chance they are a low survival type, causing them to save very little relative to what they would save if they knew they were a high type: ambiguity causes a painful "undersaving" problem among the poor who are the high survival type.

Note: Plus marks are consumption under ambiguity. Circles are consumption when the survival type is known in advance.

Our welfare calculations are **conservative** for two reasons:

- Individuals maximize expected utility (they are not ambiguity averse).
 - Dimmock, Kouwenberg, Mitchell, and Peijnenburg (2016) estimate that half the population are ambiguity averse. Distaste for ambiguity would further increase the welfare cost of ambiguity.

Our welfare calculations are **conservative** for two reasons:

 Individuals maximize expected utility (they are not ambiguity averse).

• Dimmock, Kouwenberg, Mitchell, and Peijnenburg (2016) estimate that half the population are ambiguity averse. Distaste for ambiguity would further increase the welfare cost of ambiguity.

No limits on cognition. Individuals have rational prior beliefs about the survival probabilities that they face, and they rationally update those beliefs according to Bayes' rule. In other words, individuals optimally cope with ambiguity.
